ORIGINAL ARTICLES.

PRACTICAL NOTES RELATIVE TO RABIES

BY N. G. KEIRLE, A.M., M.D.,
OF BALTIMORE;
DIRECTOR OF THE DEPARTMENT FOR THE PREVENTIVE TREATMENT OF RABIES, COLLEGE OF PHYSICIANS AND SURGEONS, BALTIMORE.

AT what time and under what circumstances should patients be advised to submit to treatment? With what material and in what manner are they treated? What risk attends treatment? If a human being contracts rabies, he inevitably dies. There are no verified cases of recovery. Three cases are recorded in which general paralysis developed during treatment. They all recovered. In one case, the treatment was not discontinued. Whether these were cases of paralytic rabies cured by treatment is a question regarding which a consensus of opinion has not been attained. Treatment should be resorted to as soon as possible. Delay is not only dangerous, but may be deadly. A physician consulted me regarding a bite upon his hand. He had already delayed ten days, awaiting the result of an inoculation experiment. He was advised to take treatment without further delay, but failed to do so. He developed rabies about as soon as the inoculated animals. Two patients were advised to submit to treatment at once. They refused, stating they would await the result of the inoculation experiment. Rabies developed almost simultaneously in both the experiment and patients. However, a number, though not treated, escape. An example of this was a child bitten severely on both arms. The dog had been experimentally demonstrated rabid.

As to risk, there is none greater than the rare and unjustifiable occurrence of abscesses. Lumps caused by proliferation of connective-tissue corpuscles are common, as is also a local or general erythema. The length of time of treatment should not be less than twenty-three days. If very severely bitten, and there is persistent induration about the wounds, it is advisable to continue treatment off and on until the induration subsides. Unless it is certain that rabies is absent, those exposed should not be held pending investigation. The affirmative result of the morbid histology, or experimental inoculation, is a demonstrated certainty. If there is a suspicion of rabies, the patient should be given the benefit of the doubt and should be treated without delay.

If the biting animal can be securely kept, it is a mistake to kill it. Treat the patient and observe the animal. If after a few days it is evidently in sound health, the treatment may be stopped. A lady seeking her stray dog visited a pound. She did not find her dog, but the good and amiable points of another dog were pointed out to her, to observe which she had to stoop over the animal, whereupon it seized and severely lacerated her lip with its teeth. This being a very dangerous situation for such wounds, she was treated at once and the dog visited for four days. It became evident that it was merely a vicious brute, and treatment was discontinued.

This question is frequently asked: What kind of serum is used in treatment? It is not serum. There is no serum antitoxin analogous to that of diphtheria. The therapeutic material used is a portion of the spinal cord of a rabbit that has died of rabies. This is rubbed up in sterile cool water. These spinal cords have been dried over caustic potash which diminishes the amount of virus, but does not attenuate it. The virus is in a condition termed fixed (*virus fixe*). This is a virus which, inoculated subdurally in a rabbit, causes rabies after six days. Before it attains this condition of fixation, it is necessary to inoculate from rabbit to rabbit until it has passed through about fifty. In the first inoculation, rabies does not develop until the completion of eleven, twelve or fifteen days. The medulla oblongata is used in the inoculations of animals. Prior to experience it seems rash to inject a deadly virus into a human body. Pasteur demonstrated its harmless efficacy. The immense gulf between scientific audacity and foolhardiness had been securely bridged with experiments. The method of treatment is subcutaneous hypodermic injections. For convenience, the abdominal region is selected.

Among fanciful methods of treatment, there is the madstone. If it adheres virus is present; if it becomes coated with green, there is virus extracted; perhaps this really is the green pus organism. Raw livers of rabid dogs have been fed to patients. The brains of rabid rabbits have been suggested as therapeutic food.

In India the entrails of an insect are administered, which causes bloody purgation. The patient is also exposed to the heat of the sun. This remedy caused bloody dejections in an inoculated rabbit, but it in no way modified the fatal result.

Bile renders the rabic virus inert, but this mixture fails to confer immunity. The destruction of virulence probably is due to cholic acid (M. H. Valée, of Toulouse, *Annales de l'Institut Pasteur*, June, 1899). Out of the body rabic virus is sterilized at a temperature of 108° F., which is the normal temperature of a hen. In this fowl, when subdurally inoculated, the disease runs a protracted course, and its medulla oblongata becomes inert, sterile. The temperature of a living, inoculated rabbit may be artificially raised until

it reaches 110° F. in its medulla oblongata, but the virus is in no degree modified by this heat, which cannot be endured, but speedily kills. The time is too short for sterilization. The temperature in the human medulla oblongata may be raised to 106° F. by exposure of the individual to dry heat of 180° F., which cannot long be safely endured, nor would it sterilize.

In the nervous system, a morbid histology in rabies is evident, but it is not absolutely pathognomic of the disease. It may be also present in other diseases, which, however, are uncommon in those animals in which rabies is common. In the *Annales de l'Institut Pasteur,* M. V. Babes of Bucharest, in April, 1892, described, in the medulla oblongata and cord, pallor of cell protoplasm, vacuolation, pigmentation and nuclear division, hyaline degeneration of nerve-sheaths and vessels and small-cell exudate. An interesting and characteristic change is observable in the histology of the ganglia, especially the intervertebral. Pathology in this country is indebted to Drs. Ravenel and McCarthy of the University of Pennsylvania for a most instructive exposition of these changes (Rapid Diagnosis of Rabies, *University Medical Magazine,* Phila., January, 1901), which consist in the breaking up of the cells bordering the capsules of the nerve-cells, which themselves are overlaid by these dispersed neuroglia cells. In many parts, the nerve-cells have disappeared. The section is bestrown with small cells.

With such histology, rabies is almost surely present. Without it, rabies is almost surely absent. In either case, treatment should be given. Absolute certainty at present is an unattainable desideratum.

In the preparation of the cords and in the treatment of patients, the technic of the Institut Pasteur, Paris, has been strictly adhered to, from which methods there are deviations. Of these the attempt to preserve cords and their virus in glycerin is very unreliable. If the glycerin is neutral and remains so, the cord may retain its virulence; but, if the glycerin undergoes change, especially if it become acid (which it is liable to do), the virus will be destroyed, and the cord rendered sterile, inert, useless.

ACTINOTHERAPY IN CUTANEOUS MEDICINE, A PRELIMINARY COMMUNICATION.[1]

BY WILLIAM S. GOTTHEIL, M.D.,

OF NEW YORK.

THE employment of light as a therapeutic agent is no new thing in medicine. The best term to employ for this method of treatment in general is phototherapy. The use of that especial form the discovery of which has immortalized the name of Röntgen is generally known as radiotherapy. Actinotherapy seems to be the most suitable designation for the employment of ordinary sun or arc light, or portions of their rays. It is to this latter that I desire to call attention.

[1] Read before the Section on Cutaneous Medicine of the American Medical Association, St. Paul, June 3, 1901.

To go no further back than the time of General Pleasanton, most of us recollect the 'blue glass craze" that then swept over the land. Wonderful therapeutic results were attributed to its use; and isolated specimens of the blue glass panes that then appeared in so many southern windows may still be seen. But Pleasanton and his followers truly saw "as through a glass, darkly"; their method was not only empirical, but was developed largely by persons who had no medical knowledge; and it never, therefore, obtained the general recognition of the profession.

The bactericidal action of light is now a well-known and established fact. Cultures of many virulent and pathogenic microbes die in a short time when exposed to properly concentrated light. Axel. L. Larsen[1] has lately gone over the ground again with the pus organisms, the colon and typhoid bacilli, etc., and has endeavored to ascertain the time required to weaken and destroy them with given concentrations of light. But this is by no means its only action and probably not even its chief one. Light irritates the cutaneous nerves, and so affects the central nervous system. It increases the oxidation processes in the cells and the amount of hemaglobin in the blood. This heightened tissue metamorphosis is possibly the factor on which its future therapeutic application will be based. The ordinary phenomena of transillumination show that light penetrates the skin. Contact photographs have repeatedly been made by means of light that has passed through the human body, notably by Kime of Fort Dodge and H. L. Mason of New York. Glass tubes containing sensitive silver salts have been introduced under the skin of animals and have shown the characteristic effects of light penetration on removal.

To Neils R. Finsen of Copenhagen, however, belongs the credit of developing the light treatment and placing it upon a scientific basis. Since he recorded the good effects which he had gotten in variola from the employment of red light several years ago, he has been an indefatigable worker in this field; and to-day his Actinotherapeutic Institute in Copenhagen has a world-wide reputation and enjoys the active support of the Danish Government.

I shall leave out of account, as foreign to the object of this preliminary paper, the work that has been done in other than dermatological fields with the new treatment, or an account of the various forms of apparatus that are employed. Suffice it to say that Helm[2], Gerson[3], Morris[4], and Finsen, Bie, and their collaborators have employed it in many varied dermatoses with a large proportion of good results. Besides lupus and the various dermal tuberculoses, in which it is possibly destined to be the treatment *par excellence*, it has been used in lupus erythematosus, psoriasis, epithelioma, acne vulgaris, rosacea,

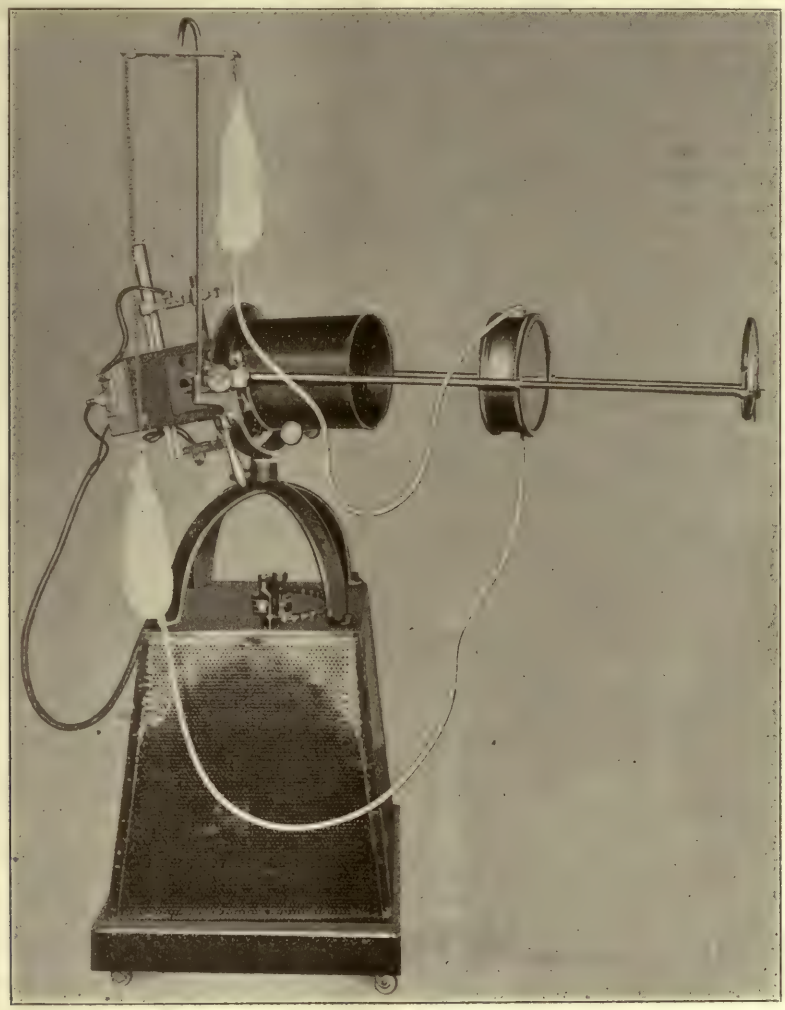
[4] British Journal of Dermatology, August, 1900.

alopecia areata, eczema, ringworm, contagious impetigo, and various ulcerations with success.

Either sunlight or the electric arc can be employed, but the former is too uncertain in most parts of our country to be relied upon. The chemical or actinic rays of the more refrangible end of the spectrum are the elements from which therapeutic effects may be expected, and we have fortunately in the electric arc a source of light which is accessible in all our large centers at any time, and which is especially rich in them. Sunlight is cheaper, of course, but it is only in regions like California or New Mexico, where it would have to be relegated to institutions where the necessary elaborate arrangements for the simultaneous treatment of a number of patients could be made. Increase of the amperage employed and reflection and concentration of all the available rays upon the area to be treated have enabled me already to reduce it very materially, and I have no doubt that further progress in that direction will very shortly be made. I now give half-hourly sittings every other day. The question is solely one of actinic light intensity.

I employ the instrument manufactured by Kliegl Brothers, of this city, and called by them



The Actinolyte.

can be relied upon for any great part of the year, that the expense of installing a sunlight apparatus would be warranted. The arc light can be employed on cloudy days, or in the evening; and this leads me to mention and dispose of one apparent disadvantage of the process. The actinotherapeutic treatment takes time; of that there can be no doubt. But I am convinced that it does not even now require the hourly sessions every day which Finsen gives his patients. Were that the case, no matter what its advantages, it

the actinolyte. It consists essentially of an arc light with the necessary arrangements for automatic action, enclosed in an iron hood. In the hood in front of the arc is a double convex condenser, adjustable for focussing purposes by means of a rack and pinion. On rods that project in front from each side of the hood is a double convex focussing lens, also adjustable. By means of these condensers a circle of light of any size can be readily obtained; of course, the smaller it is the more intense is the illumination. The

hood is swung in such a way that it can be raised or lowered, or swung laterally or vertically, thus making it possible to project the light spot with exactitude upon the area that is to be treated. On the front bars and between the hood and focussing lens is a cell for the purpose of containing the fluid to cut off the heat rays. This can be filled with distilled water or methylene blue or alum solution; or it may be connected with the two water-bags for which arrangement is made so that a continuous stream of heat-absorbing fluid may flow through the cell. So far I have found plain cold water without continuous flow quite sufficient to prevent any unpleasant heat effects from the concentrated light. The base of the instrument contains a suitable rheostat, with a selector on top. Either the continuous or the alternating current may be employed and from 25 to 55 amperes of current can be used. The candle-power obtained varies, of course, with the amperage. With a concentrated circle of light it runs from 20,000 to 60,000.

I am not prepared as yet to make a definite statement of the results obtained with the treatment save in two cases. In one patient with extensive lupus vulgaris they promise to be brilliant. The only area that has been treated, some two inches square, presents a marked contrast to the other locations where the disease is progressing. It is almost white, only two or three lupoid nodules remain, and they are disappearing. And this has been accomplished without ulceration, or even inflammation; the process has been entirely one of interstitial absorption. All the other areas are characteristically infiltrated and scaling. The patient has had absolutely no other treatment.

The second case is one of obstinate tertiary syphilitic ulceration of the leg. The light has apparently had a very good effect in stimulating the indolent glazed ulcer, so that it is now nearly healed, after resisting other internal and local treatment for weeks.

Now as to the advantages of the method. First and foremost it is eminently conservative. It causes no radiodermatitis, ulceration, or loss of hair, such as too often, though sometimes necessarily, occur under the Röntgen treatment. I do not know of the record of any serious trouble from its employment. Finsen rightly lays stress upon this point; and to dermatologists it is of special importance, since many of the affections that they are called upon to treat occur upon the face. In the second place it is entirely painless. This is a great desideratum, more especially in dealing with women and children. Third, it is effective. New as the method is, there is already concurrent testimony from a sufficient number of competent observers to demonstrate that we possess a powerful therapeutic agent in concentrated light.

Leaving to others the study of the effects of actinotherapy in the general conditions and affections of the internal organs in which it may prove useful, it is to be presumed that by dermatologists it may be employed in the various skin affections which are dependent upon micro-organic or parasitic infection, or where increased tissue metamorphosis is a desideratum. Lupus vulgaris, lupus erythematosus, mycotic eczema, trichophytosis, favus, impetigo, furunculosis, tuberculosis cutis, epithelioma, mycosis fungoides, blastomycosis, actinomycosis, and similar affections are the diseases in which it is likely to prove useful.

144 West Forty-eight Street.

IDEALS IN PHYSICAL EDUCATION.

BY D. A. SARGENT, M.D.,
OF CAMBRIDGE, MASS.

IN reviewing the achievements of the past century in physical education we cannot help being deeply impressed with the substantial progress that has been made. You are all familiar with the general history of the subject, in this country at least, and I will not take your time this morning in enumerating dates, or recounting the epochs and events that have marked the successive stages in the advancement of our cause. My purpose is rather to take up the status of our work (physical education) at the present time, to consider some of the drifts and tendencies that are shaping its course, to make a critical review of some of the evils that beset us, and then see if we cannot find some common ideals towards the realization of which we may direct our energies.

In considering the present status of physical training in the United States we find it established in some form or other in 270 colleges and universities—98 are doing organized work, 72 require physical exercise and 24 give credit for it in the course which counts for a diploma. About 300 cities have introduced physical exercises into the public schools, and 100 of them have special teachers. There are about 500 Y. M. C. A. gymnasiums in different parts of the country, with a corps of some 300 physical directors and 80,000 members. The North American Turnerbund has some 300 gymnasiums and about 200 instructors and some 45,000 members. There are perhaps 100 athletic club gymnasiums of one description or another and a few out-of-door and public city gymnasiums. Then there are many gymnasiums in private houses, churches, hospitals, sanitariums, army and navy depots, police quarters, engine-house stations, mission houses, industrial schools and many other institutions to the number of several hundred. In addition to this form of physical training there are a great variety of special athletic clubs for boxing, fencing, bowling, boating, canoeing, swimming, bicycling, etc. Then there is golf, tennis, baseball, football, with their ardent devotees and numerous following, together with the more passive forms of exercise such as riding, sailing, driving, etc., which have many admirers.

Taking all the sports, games and well-established forms of exercises into consideration, it is safe to affirm that they represent millions in capital invested and affect the lives of millions of our people. The amount of money which a people are willing to spend in the furtherance of a movement is a pretty good indication of its value in their estimation, though if judged from an educational point of view this value would probably be considerably discounted. If we were to estimate the value of the century's efforts in physical training by the effects produced, the problem would be a difficult one on account of the many factors involved, and the increasing number of influences that tend to neutralize all the good effects that might be derived from systematic physical exercise. Those of us who are engaged in making physical examinations know the effects which the practice of special forms of exercise have upon the individual, and it is fair to presume that the same exercises practised by many people will tend to have similar effects. Thus, when a great popular interest sweeps over the country for bicycling, lawn tennis, golf, boxing, or football, the tendency will be to produce among the masses the same mental and physical characteristics that are recognized in the individual devotees of these popular pastimes. It is hardly necessary for me to dwell at this time upon the special effects of these forms of exercise for you are all more or less familiar with them. No one would be regarded as perfect from a mental, moral, or physical point of view, and yet they have produced a most profound effect upon our people. Bicycling, lawn tennis, and golf have been especially valuable to our women, inducing many to exercise who never exercised before. These three sports have probably done more to overcome the evils of tight clothing than a whole century of preaching and lecturing on this subject. Boxing, football, basketball and other antagonistic games have done a great deal to lessen the evils of over refinement and excessive sentimentality, and they may be conducted in such a way as to develop a firm character and a manly spirit. But there are certain inclinations connected with the development of competitive sports and antagonistic games that are not only detrimental to physical training in its best sense, but are also demoralizing to our youth and to the public in general.

Let us consider some of these drifts and tendencies. Thirty years ago amateur baseball was at its height in America, and there were well-organized clubs in nearly every city in the Union. To-day there are a very few amateur baseball clubs outside of the colleges, and the interest in this once popular sport is declining in our institutions of learning. Professional baseball has superseded amateur baseball in popular interest, and although the game is just as beneficial from a physical and recreative point of view as ever it does not have anything like the following it once had. The interest in college boating culminated in 1875, when thirteen crews were represented at Saratoga. In some colleges this sport has been abandoned altogether. In a few institutions it has been re-established, and in some, especially at Harvard, there is a great revival of interest in boating, as many as twenty eight-oared crews being on the river at one time. The practice of archery was quite generally established in this country in the early seventies, and there were numerous clubs of both sexes that rallied around this form of recreative exercise. The interest culminated in 1879 and at the present time there are few archery clubs in existence. The so-called higher gymnastics attained their greatest prominence in the colleges and city gymnasiums in the early seventies. Boxing and wrestling contests attained their greatest popularity at Harvard in 1883, '84 and '85 and are now practically abandoned, although there are two instructors in boxing regularly employed at the gymnasium. The interest in lacrosse and cricket has waxed and waned, but the games have never been entirely abandoned. Field and track athletics have a strong following in the vicinity of New York, Boston and Philadelphia, but attract small audiences and little attention in the colleges and other communities compared to what they did a few years ago. The great city athletic clubs, which once fostered track and field athletics, now seldom have any representatives from their own membership in the public contests, and confine their attention to exploiting the athletic abilities of outsiders for the entertainment of their regular members. Some of these athletic clubs, notably the Boston, act as patrons for school and college athletes, and do a great deal to encourage the practice of out-of-door sports and systematic exercise among their junior members. Many of these city athletic clubs, like the Orange of New Jersey, Washington, Detroit, St. Louis, Providence, Pastime in Brooklyn, Manhattan in New York, Staten Island, Fitchburg, Nationals, Louisville, Philadelphia, etc., have been given up entirely or turned into social clubs.

Notwithstanding the rise and decline of interest in many of the popular sports and exercises, there never was a time in our history when so much attention was given to sports in general as at the present day. As the interest in archery, roller-skating and croquet and boating declines, the interest in bowling, bicycling, golf, canoeing or some other sport increases. Then again, the interest in certain sports, although less intense, may in reality be very widespread and be participated in by a great many people.

Now the important question is, what are the factors which cause some sports to decline and others to be perpetuated in popular favor? In answer to this question we are forced to admit that fashion plays a very prominent part, bringing into vogue at one time sports which have but few valuable features, and sweeping away at another time exercises of the greatest importance. Some of the special forms of exercise like archery, fencing, Delsarte, etc., may be taken up as society fads, and be rushed for a few seasons and

then become obsolete. Even the more serious forms of exercise are sometimes taken up by society because they are thought to be the "proper thing," without regard to their hygienic or educational value. In fact, I should be rather loth to admit to this semi-scientific association how much of our work is without scientific or artistic value, because it is governed so largely by fashion and caprice. Again the spirit of emulation and competition which we try so hard to foster and cultivate has its limitations, and it is a serious question just how far it can be carried without detriment to the cause we are striving to advance. A high spirit of emulation breeds rivalries and enmities and often stirs up bad blood and leads to the establishment of more or less permanent factions which may work great harm to a school or club. This is especially likely to be the case where competitions are confined to members of the club or to the different classes of a school or college. What discussions upon religion and politics are to social clubs, so are athletic contests to athletic clubs if the contests are limited to members. The hardest struggles on the athletic field are frequently between classes or members of the same institution for positions on class or university teams. The feelings of bitterness and enmity often engendered by these hard contests in schools and colleges are softened and assuaged by the thought that knocks, strains and bruises must be endured in practice in order to enable the chosen school, college or university team to vanquish its rival from some other school, college or university. In this way a feeling of unity and solidarity is often established in an institution, which might otherwise be broken up by feuds and dissentions. It is the lack of this feeling of unity on the part of the city athletic club, and the unwillingness of its members to endure the hardships of training for the severer, yet only contests which the other members care to see, which makes these clubs after a few years fall apart simply from lack of any common interest to bind them together.

Another disrupting influence is the establishment of too high a standard. This is one of the evils of professionalism, and really marks the underlying difficulty of settling who is and who is not an amateur. The poorest professional must be a better performer than the best amateur in order to constitute himself a professional and be able to receive money for his services. But the receiving of money is a secondary consideration which follows the presumption of superior merit. This results from long and persistent practice or training such as a person is obliged to undergo in preparing for a life's profession or occupation. When therefore students, clerks and young men who work with their brains rather than with their muscles are urged to practise certain exercises or sports as a means of improving their health and physique, and are offered prizes or trophies of victory as incentive for them to train and compete, one of the first essentials of a fair contest is to see that those who entered the competition are of the same class or on somewhere near the same footing. Now, if the contest is in rowing and those who make a business of rowing are allowed to enter, the conditions would be unfair, as students who are engaged in their studies, or clerks with their bookkeeping through the working hours of the day, and who only take up rowing as a recreation or pastime, cannot compete on anything like equal terms with professional oarsmen. It would be just as absurd to expect the professional oarsman to compete on equal terms with the student in solving mathematical problems or with the clerk in bookkeeping or penmanship.

When, however, sports and pastimes are pursued with so much intensity as ends in themselves, rather than as means to an end, and the devotees give so much time to practising them that they haven't time or energy enough left to give to other pursuits, these persons are just as much professionals in the true meaning of that term as they would be if they received money for their services. These are the type of athletes that have been supported and exploited in the past by some of the large city and university athletic clubs. Although they have won prizes for their clubs, I can hardly believe they have won honors, indeed I am sure that this style of athleticism has done great injury to the cause of physical training. First, by placing all the records so high that bona-fide amateurs will find great difficulty in surpassing them; second, by discouraging and literally driving out of existence the smaller clubs that could not afford to follow the same tactics; third, by causing a decline in active interest among the members of these clubs who cannot give the time and attention from their business that will enable them to compete with the performances of star athletes and who, therefore, do not compete at all. As long as the public is content to see the best performances without regard to the status of the competitors, there will always be a tendency towards professionalism which will have to be guarded against by very stringent rules. One of the best ways of meeting this objectionable tendency in school and college athletics is for the authorities to insist that all contestants must not only attend to all of their school and college exercises, but they must give evidence of having done a certain amount of work and attained a certain rank therein. If the school curriculum is what is ought to be, this will insure that the students will not give too much time to their athletics and that the work that they do engage in will tend to give them a sound mind as well as a strong body.

I have dwelt at some length upon this tendency of antagonistic sports and highly competitive games to exterminate themselves, when not properly managed, because I deem it of the greatest importance that this fact should be thoroughly understood. There is no use denying the fact that athletic contests afford a stimulus to effort to a great many boys and young men, and even to girls and young women, which no other forms

of exercise can give. The problem is how to control these sports and yet keep up the interest, how to eliminate the evil and yet preserve the good. We have seen that when the competition was restricted to one class, school or club, hostile factions were formed and bitter rivalries engendered. Much of the hard feeling and enmity that existed between school and college classes years ago, when the practice of hazing was in vogue, were greatly intensified by class contests in football, rope-pulling, cane-rushing, etc. This feeling of enmity between classes is now fortunately a thing of the past in most institutions. I am not so sure, however, that it has not been transferred and even grown to a greater degree of intensity between rival schools and colleges, judging from the nature and tone of many of the alumni speeches that have been made and reported during the past winter. The rivalry in antagonistic games in many of our schools and colleges has now become so fierce and the desire to win has become so overpowering that there is not a little danger that amicable relations between some of these institutions may be overstrained.

One of the great charms to me of our Association meetings is the opportunity presented for seeing those who are engaged in the same work in rival schools and colleges, and in learning from experience instead of hearsay that they are not fiends, ogres or cannibals, but really good-hearted fellows having the same high aims and noble motives as ourselves, though they may have different ways of showing them. When we ask a friend to assume to be an enemy in order that we may arouse our fighting spirit and practise our animal instincts upon him, it is not a little strange that the imaginary attributes which we repeatedly give to him, are after a while difficult to efface. This is especially so if the fancied realism adds so much to our fierceness of attack and defence as to enable us to win a victory. A man instinctively shrinks from falling upon another man's head under the ordinary circumstances of life, but a man so considerate of an opponent's head or person would not make a successful football player. When the papers were filled with denunciations of the West Point cadets for their rough and cruel practices upon under class men, it did not occur to the general public that these are qualities that must necessarily be bred into the man who would become a professional soldier. A much more agreeable way for us to become reconciled to the stern qualities in our young men, especially if we wish to raise an army, is to attribute these rough, cruel and even fiendish qualities to those who happen to be for the time being our enemies. We have all read about the inhuman cruelties of our Southern brethren during the Civil War, the barbarous cruelties of the Spanish soldiers, and the fiendish conduct of the Chinese Boxers and the Filipinos. By attributing diabolical qualities to an opponent we may excuse ourselves for trying "to do him up" or "put him out of the game." These are simply the remnants of primitive characteristics, possessed by our early ancestors, when those who were not members of the tribe were enemies of the tribe, whom it was one's first duty to wound or kill. When rival boxers deliberately try to "knock each other out," and friendly baseball players "spike" a runner, or throw dirt in a baseman's eyes; when the fair devotees of basketball hiss every attempt of the visiting team to make a goal; when grave and dignified professors rush up and down the side lines of the football field shouting, "down him," "kill him," and delicate ladies who but a moment before shrunk from witnessing the "brutal" game, with flushed cheeks and staring eyes wildly shriek their approval, one might reasonably ask if this, also, is not an exhibition of some of the recurrent traits of our barbaric ancestry.

Of course these are exceptional occurrences, but if you have any real doubt as to the passions which are swaying the minds of most of the spectators, as well as the participants, during an exciting football game or boxing match, just watch the faces of the audience during these antagonistic exercises. To be sure there is the joy of victory to the side that wins, there is also the chagrin of defeat to the side that loses, and it is a question if the prolonged depression that follows defeat does not more than offset the temporary pleasure of victory. It is certainly true that the feelings engendered between institutions by violent athletic contests does not tend to unite them, when harmonious relations and unity of spirit seem altogether desirable. We have seen that when athletic contests were confined to the members of different classes in the same institution that the rivalry became intense and the spirit bitter, and that the only way to relieve this tension and hard feeling was to unite in competition against some other institution. As this movement, which has now been in operation for twenty or thirty years in some of our colleges, is beginning to breed the inevitable bitterness of feeling that sometimes finds expression in a phrase that consigns a whole institution to the infernal regions, the question arises whether these rival colleges cannot unite against some common enemy or institution and thus work together in harmony. The union of Harvard and Yale against Oxford and Cambridge in their athletic games in England, and the American team at Paris and at Athens, are illustrations to the point.

In arranging for international contests to take place every four years in which the winners in the intercollegiate contests could be represented, a new interest and a new zest would be given to athletic games, and their real significance might be brought home to our people, for they would soon learn that this was one of the best means of preserving our National Unity. The rivalry that exists between nations is a fundamental one, and is based largely upon differences in race, blood, nurture and environment. There is no natural rivalry between States, cities and institutions in our country founded upon the personal qualities of those who were born, bred and educated there-

in. Would that there were. A city baseball nine or a college athletic team may be made up of representatives of all parts of the country. Whether these men are successful athletes or not will depend largely upon their own superior natural abilities, their previous training, and the way in which they are handled or managed. Why a city, a college or a community should pride itself upon the achievements of a baseball nine or an athletic team which it never produced is one of the things that I have never been able to comprehend. The only justifiable ground upon which any such pride could be based is that these athletic teams represented the return of a system of physical training open to all, in which the victorious athletes had had to fight their way up, step by step, through preliminary contests until they won a place on the boat or university team. And even then the only thing worthy of recognition in these prolonged contests by a great university would be the triumph of better blood, better brains, better hearts, better lungs, better nerves, muscles and tissues. If the totality of these valuable essentials to life, health, happiness and success have not been increased in the college community at large by the influence of athletics, then these much lauded exercises may be considered not only of doubtful value but even of positive injury to an institution of learning. Happily the average physique in our secondary schools and colleges is improving slowly.

At the present day every alumnus rejoices in the athletic victory of his school or college team, because he thinks the public will consider the achievements of this team a fair representation of what his institution is doing for the physical training of its youth. How seldom this is true! In intellectual training all school men are required to come up to a certain minimum standard of excellence before they can enter college, and again before they can receive their diplomas. There is no such incentive to keep the mass of students up to a required physical standard, and the gulf between the lowest and the highest is great indeed. A few years ago the college gymnasium directors, believing that a moderate degree of physical strength was the fundamental basis, not only for all forms of athletics, but for health itself, decided upon a uniform system of strength tests by which to gauge certain functional powers in their respective pupils. The test consisted of an all-round trial of strength of back, legs, arms and chest, in which the sum total of the several trials was to represent the total strength of the individual. After the candidates for all the athletic teams have been chosen, a great many men who desire to have something definite to compete for, are left without any incentive. One object of the college strength test is to furnish an incentive for a large number of men to keep up their physical exercise by giving them an opportunity to record their improvement and compare it with others measured by the same standard.

The method adopted has been in use at some of our colleges for over twenty-two years, and now offers a basis of comparison between two generations and the individual records of over twenty-five thousand persons. In order to encourage a great number to compete every college in the league agrees to send in to the committee a list of its fifty strongest men, and the college having the fifty which makes the largest total wins the highest honors in this contest for the year. Last year Columbia was first on the list, with a total of 59,489.4 points in which each of the fifty men represented averaged 1,157.2 points. Now, the point which I wish to make is that, notwithstanding the high average made by the first fifty representing Columbia and the other colleges in the league, in all probability the average of all the men examined would not be much over 500 points. In other words, fifty per cent. of all the men examined would fail to make a strength test which was equal to half of that surpassed by the first fifty. While if we make comparisons with the individual men who head the list, we find that over half of all those examined fail to make a test equal to one-third of that attained by the leaders. Now these facts emphasize three things, the stimulating effect of a comparative record or contest upon a considerable number of men, the remarkable increase in functional power that can be attained by systematic training, and the large number of college men who never begin to realize one-half of their possibilities in the way of physical improvement.

The great objection to all forms of athletic competitions and strength contests is that after a while, as the standard rises, they are likely to be pursued as ends in themselves, as I have stated before, rather than as means to an end, which is the betterment of the whole organism. But unfortunately this objection is not inseparable from mental contests, and in both instances those men come to the front whose constitutions are best adapted to stand the strain to which they are subjected. By this method of selection our higher schools and colleges are fostering two distinct types. One type devotes itself to the supreme development of the mind, and the other type to the supreme development of the body. The latter type is best calculated to survive, because it has to meet certain mental requirements of the faculty. But neither type represents the average student, and yet it is the condition of the average student who shows what our schools and colleges are doing for the country.

The more experience I have in teaching physical training and the more I observe its results, the more I am convinced that the highest ideal for which we should strive is the improvement of the individual man in structure and in function. This was the conclusion that I came to some twenty-five years ago, and time and experience have given it confirmation. With this ideal in mind all the diverse forms of exercise and games, all fads and specialties, all methods and systems may be weighed in the balance and credited for what they are really worth. For it is not

a runner, a jumper, a boxer, a ball-player, an oarsman or a gymnast that we are trying to produce, but the highest type of a physically perfect man. This forbids excessive development in any one direction, which specialists are constantly striving to attain. It also makes overexercise and overtraining inconsistent with the object in view. It furnishes a constant incentive to well-directed efforts and right methods of living. It is not necessary to hunt for a competitor, for one is always in competition with himself, endeavoring to make his condition to-day better than it was yesterday and so on from week to week and from month to month. If one wants an opponent, he accepts him as a friend. For, as Burke says, "He that wrestles with us strengthens our nerves and sharpens our skill. Our antagonist is our helper." The great thing to be desired and attained is that prime physical condition called fitness—fitness for work, fitness for play, fitness for anything a man may be called upon to do. Is not this a condition worth striving for? How few of us realize the dignity and importance of the work in which we are engaged. Trying to assist Nature in developing and perfecting her handiwork, not simply mending bones, patching wounds and relieving functional disturbances, but trying to lift man on to a higher plane of living, by improving the structure of his bones, muscles, nerves and tissues, and increasing the functional capacity of his whole organism. This is the highest kind of constructive work, in which the building of all other material structures sinks into utter insignificance. If there are those among you who sometimes get disheartened and discouraged because you think your particular branch of service is not appreciated, I trust you will let this ideal take possession of you.

Drink into your very soul, the true aims and noble purposes of your profession. Then if you do not feel inspired to go on with your glorious work with renewed courage and greater energy, you are not made of the stuff of which good teachers of physical training are made. If you do become possessed of the true ideals all of your work will assume a new significance to you. Balls, bats, wands, Indian clubs, dumbbells, chest-weights, ropes, ladders, bars, and all the apparatus of the gymnasium will take on a new importance.

Free exercises, dancing steps, plays, games and "sleights of art and feats of strength," even the schoolboy's "stunts," all will be brought under tribute and made to aid you in getting hold of some indifferent soul, and inducing him to make efforts for himself. All criticism against childish sports, trivial plays and undignified movements and exercises will be simply laughed to scorn, for what dignity has any movement or exercise except the dignity of the mind that directs it? Something of this spirit must have possessed the minds of Agesilaus and Socrates of old, who did not disdain to practise the child's play of "riding a stick" for exercise.

It is the same spirit that induces many over-brain-worked business and professional men, many closely confined clerks and shop girls, to take regular systematic exercise at their homes or boarding-places, when golf, tennis, the bicycle and the gymnasium are inaccessible. And I regret to say that it is a lack of this spirit that puts so many of our college athletes out of condition after they have entered upon their life's work. Finding no opportunity to practise their favorite sport, they find no incentive for exercise of any kind, and frequently break down in health for the want of it. There are scores of such men in New York to-day, and their early breakdown is not unfrequently attributed to overindulgence in college athletics. In some instances this may be true, but the fundamental weakness in the whole athletic movement at the present time is a failure to recognize the primary objects for which athletic exercises are fostered and encouraged—in other words, a failure to recognize proper standards and high ideals. In consequence of this difference of aim and motive many of us are kept busy protecting students against the excesses of some form of athletics while in college, and defending athletics against the attacks of some students after they leave college. If, therefore, we would preserve exciting games and competitive exercises as a part of our stock and trade as a means of physical development, we must be constantly on our guard to detect abuses and withstrain excesses. If, on the other hand, we would avail ourselves of the many excellent exercises which from their nature are not likely to be carried to excess, we must never weary of our efforts to arouse in our pupils an ambition and incentive to try them for the development of their own better selves. This is the vital principle back of all of our work, and if the teachers of physical training will imbibe a little enthusiasm for physical perfection, for its own sake, and put a little of the spirit of helpfulness into their daily work they need never despair of appreciation or employment, for the world is waiting for their efforts. With these ideals in view we may look in the future for the advancement of our cause with reasonable hope and joyous expectation.

THE EARLY OPERATIVE TREATMENT OF ACUTE MASTOID INFLAMMATION.

BY EDWARD B. DENCH, M.D.,

OF NEW YORK;

PROFESSOR OF OTOLOGY IN THE UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE; CONSULTING OTOLOGIST TO ST. LUKE'S HOSPITAL; CONSULTING OTOLOGIST TO THE NEW YORK ORTHOPÆDIC DISPENSARY AND HOSPITAL; ATTENDING AURAL SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY.

AN acute inflammatory process involving the mastoid may occur as a sequel of a severe cold in the head; it may follow one of the exanthemata, or it may be found as a complication of any acute infectious disease. In this later connection the recent epidemics of the grip should be mentioned

as a particular cause of this condition. It is a clinical fact that the aural complications vary decidedly with each epidemic of the grip. During the second year in which this disease was epidemic in this country, mastoid complications were exceedingly frequent. This has also been true in the epidemic of last year, and is true at the present time. It is a somewhat curious clinical fact that during the epidemic of the present year the aural involvement has been probably more severe than in any of the preceding epidemics. In almost every case of acute inflammation of the middle ear which I have seen following the grip there has been some mastoid tenderness. I do not mean by this statement that every case has required operation, but in each instance there has been decided evidence of a congestion of the mastoid very frequently passing into an acute inflammatory process.

The symptoms of mastoid involvement are so well known that they need hardly be mentioned. In the first place, the pain is apt to be severe; there is headache and sleeplessness and, in children, a considerable rise in temperature. I lay stress upon this one symptom in children because in adults temperature is of but little value in determining the presence or absence of any inflammatory process within the mastoid. In some of the most severe cases which I have observed in adults there has been no rise in temperature. While the pain is usually a prominent symptom, it may not be very severe. In adults sleeplessness is one of the most important symptoms, and in any case of middle-ear suppuration where the patient is unable to sleep, although he may not attribute this to pain, it is important to observe carefully the condition of the mastoid. The pain may be so slight that in some cases the patient is able to follow his ordinary vocation complaining simply of slight discomfort in the ear, of an aural discharge and of restlessness or discomfort at night, but of no severe and intense pain. In one case, which I saw in consultation, the patient had not been absent one day from his business, yet on examination I found a perforation through the upper portion of the membrana tympani, sinking of the upper and posterior wall of the external auditory meatus, and tenderness over the mastoid region. Further examination revealed a diffuse, brawny mass in the neck below the tip of the mastoid process. This swelling was tender upon pressure. The aural discharge in this case had been but slight, and the patient had suffered so little discomfort that he was astonished when I told him that immediate operation was necessary. He insisted upon delaying the operation, and as he lived at a considerable distance from New York he was finally operated upon by an eminent colleague in a neighboring city. Less than one week after he came into my office I learned from the family that he had died of acute meningitis, the intracranial involvement having occurred before the operative procedure was undertaken. I narrate this case simply to show the rapidity with which mastoid involvement may occur, and how insidious the advance of the disease may be. Bearing in mind the possible fatal issue in such cases, it seems advisable to urge early operative interference in all cases of acute middle-ear inflammation, and especially in those cases following the grip, or, in fact, any acute infectious disease.

The first step is the early and free incision of the membrana tympani, the incision being extended well out upon the upper and posterior wall of the canal so as to relieve any tension in the mastoid process. Such an incision is best made under general anesthesia, and nitrous oxide is the ideal anesthetic for such an operation. If after an incision of this kind, all tenderness does not subside within a few days I am in favor of opening the mastoid process.

Regarding abortive measures for the relief of inflammation of the mastoid, I can only say that, in my hands, they have proved most unsatisfactory. A few years ago it was my practice, after incising the membrana tympani, to apply either the Leiter ice-coil or the aural ice-bag for a period of from thirty-six to forty-eight hours in all cases in which there was the least evidence of mastoid involvement. Recent experience has taught me, however, that these abortive measures serve to conceal and mask the symptoms of the inflammation without actually relieving it. I think we should be very careful in all cases of this kind about employing measures to abort the inflammation. In many instances I am positive that these abortive measures have simply relieved the pain temporarily, and that the patient has passed from observation only to suffer at a later period from some severe complication of the mastoiditis. In one instance which came under my observation the patient had been treated with apparent success by means of the ice-coil. About six weeks later I operated upon him for tempero-sphenoidal abscess. Although the man ultimately made a complete recovery, I do not believe this complication would have followed had the mastoid been opened when he first came under observation. In a second case, the patient made apparently a complete recovery from an acute mastoiditis under the use of the ice-coil; all tenderness disappeared and all symptoms of mastoid involvement were absent when he left the hospital. Some weeks afterward he again came under observation, and a large epidural abscess was found in the posterior cranial fossa.

Turning now to those cases which are operated upon early, I would say that in no instance have I ever opened the mastoid process without finding considerable destruction of osseous tissue. While attempting to be most conservative in these cases I have always found that I have erred on the side of conservatism—in other words, that it would have been better had I operated at an earlier period. It has never been my experience to find a mastoid in such a condition that I would have been warranted in delaying the operative procedure.

Regarding the use of local blood-letting for

aborting the local inflammation, I believe it is absolutely contra-indicated in all cases. The local abstraction of blood from the mastoid region may temporarily diminish the pain, but I do not believe that in any case it tends to abort the inflammatory process. The symptoms are merely masked and the patient is much more liable to suffer from some serious intracranial complication than if the measure had not been employed.

We now come to the consideration of the symptoms which warrant operative interference upon the mastoid. Of these, local tenderness is, I think, the most constant symptom and the one most to be depended upon. This tenderness is usually found over the region of the antrum. Tenderness at the tip of the mastoid is not, in my experience, as signficant of an inflammation within the osseous structure as is antrum tenderness. As before stated, tip tenderness has been found, in my experience, in almost all cases of acute middle-ear inflammation during the recent grip epidemic. In a large number of these the tenderness has increased, gradually spreading over the mastoid until the antral region was reached. Many of these cases have been operated upon early, and in every instance softened bone has been found, and, in a number, extensive destruction of osseous tissue with an accumulation of pus in the mastoid cells. Some of these cases have yielded to very free incision of the membrana tympani, thus securing free drainage of the middle ear. After incision the ordinary antiseptic irrigation has been employed. The tenderness has, however, been quite slow in disappearing. I mention these facts to show that we cannot depend upon tenderness alone as indicative of mastoid involvement; other symptoms must be present in order to warrant operative interference. In any case, a narrowing of the deep meatus should be regarded as an exceedingly grave sign. If this sign is persistent, and occurs in conjunction with mastoid tenderness, the surgeon is not warranted in delaying the operation.

When we come to consider the dangers of operative interference, we find that under proper antiseptic precautions the dangers from mastoid operations are practically *nil.* It goes without saying that no surgeon should undertake this operation without making the same careful aseptic and antiseptic preparations which he would make for entering the abdominal cavity. The field of operation must be carefully shaved, the parts thoroughly cleansed by scrubbing, and an antiseptic dressing applied for a few hours before the operation whenever this is possible. The external auditory meatus must be thoroughly irrigated with a solution of bichloride of mercury, 1-3,000, and the canal occluded by means of a tampon of iodoform gauze. Both the ear and the field of operation should be completely covered by a moist antiseptic dressing, and this should not be removed until the patient is under the anesthetic. In operating upon these cases I always make it a rule to do a complete operation. I am well aware that some eminent surgeons have made the statement that complete exploration of all the mastoid cells is unnecessary, especially in the so-called influenza cases where we find early involvement of the superficial mastoid cells. Some even go so far as to advise that the antrum shall not be opened unless it is absolutely certain that it is involved. My own experience has been that it is always wise to enter the antrum in every case. A primary mastoiditis is a condition rarely found, and although the superficial cells may contain more pus than those lying deeper, the infection, I believe, must almost invariably come from the middle ear. The reason that in some instances more pus is present in the superficial cells than in the underlying ones is to be found in the varying topography of the mastoid in individual cases. I have found frequently, and especially in my recent operations, that cells very remote from the middle ear may be filled with pus although the remainder of the mastoid may be but slightly involved. For this reason I advocate the performance of a complete and thorough operation in every instance. The entire pneumatic structure of the mastoid must be investigated, the delicate walls of the cells broken down and the operation not considered complete until firm, dense bone is reached in every direction.

As the primary step of the operation, I earnestly advocate opening the antrum and establishing a free communication with the middle ear. The topography of the mastoid varies so greatly in different individuals that unless this is done it is impossible for the operator to thoroughly remove every focus of infection without running the risk of invading some important region—I refer to accidentally entering the middle cranial fossa or the unintentional opening of the lateral sinus. The possibility of such an accident renders strict attention to aseptic technic absolutely necessary. While it is usually possible for the operator to avoid the accidental opening of the lateral sinus, and while he will seldom enter the middle cranial fossa without intending to do so, such accidents may occur even to the most skilful operator. If the aseptic technic has been perfect the result of any accident of this kind will in no way influence the future progress of the case. If on the contrary, absolute cleanliness has not been observed, either accident may be followed by most serious consequences. If a large opening is made into the mastoid, the accidental wounding of the sinus is not a serious matter; the hemorrhage can be controlled with pressure applied with a pad of gauze held by the assistant, and the surgeon can proceed with the operation. If, on the other hand, a small opening is made in the mastoid, and the sinus is accidentally entered, it is impossible to finish the operation and at the same time control the hemorrhage. Again, it should be remembered that, even in cases in which there seems, on examination, to be but slight mastoid involvement, the inflammatory process may have been so extensive as to

have already invaded the lateral sinus, or to have caused a localized infection of the meninges. Under perfect surgical technic the discovery of such a condition enables the surgeon to immediately relieve the patient, while, on the other hand, if the operation is conducted carelessly, the intracranial involvement must be a very serious matter. The possibility of intracranial involvement in even the most acute cases is certainly an argument for thorough and complete operation in every instance. Another reason for making the operation extensive is that the large opening in the bone enables one to determine whether or not any intracranial inflammation is actually present. All softened bone is removed, and each area of softening is followed until firm bone is reached. If this is done, there is no possibility of the surgeon overlooking an extension of the infection to the intracranial structures. If, on the other hand, a small opening is made, and softened bone simply curetted out through this, the parts are not under immediate inspection, and an extension of the inflammation may be overlooked. I remember one case, recently operated upon, in which the patient had only been ill for about eight days, and yet a perforation had occurred through the roof of the *aditus ad antrum* into the middle cranial fossa. It was easy enough to isolate this region in the dressing of the wound and prevent any further infection. Had the mastoid operation been less extensive, however, this opening would certainly have been overlooked, and infection of the meninges might have taken place.

Bearing in mind, then, the rapid course which mastoid involvement may follow, and remembering how quickly infection of the intracranial structures may occur, I am strongly in favor of operating upon these cases very early, and in limiting all measures of abortive treatment to those cases seen in the earliest stage, and in which there is simply a fear that mastoid involvement may occur. When there is well-marked mastoid tenderness, and when there is narrowing of the meatus, I do not believe that it is wise to attempt to abort the inflammation by the local application of cold or by the local abstraction of blood. It is much better to keep the patient perfectly at rest and under observation for a day or two without the use of any abortive measures than to mask the symptoms by external applications. If at the end of twenty-four or forty-eight hours the condition is not changed, the surgeon is certainly warranted in operating upon the mastoid process. An exploratory operation in this region is certainly as justifiable as exploratory laparotomy. At the present day, the surgeon does not wait until he is absolutely certain that a case of appendicitis will not recover without operation; he does not delay until the patient is in a desperate condition, but by early operation prevents the patient's condition from becoming serious. I believe the aural surgeon should adopt exactly the same rules. If a case is doubtful he is fully justified in doing an exploratory operation. If nothing is found, no damage has been done. If this rule is observed I believe that many lives will be saved which would be lost if the abortive plan of treatment is followed.

17 West Forty-Sixth Street.

SALIENT POINTS IN AN EPIDEMIC OF TYPHOID FEVER BASED UPON FIFTY-FIVE CASES.[1]

BY WM. J. CRITTENDEN, M.D.,
OF UNIONVILLE, VA.

IN this paper I do not propose to read a compilation from authors, nor will I quote a long line of statistics. I do not know that it will be of much interest to the other practitioner of medicine, but to the younger practitioner, who is just stepping on the threshold of practice, it is most respectfully dedicated.

During the epidemic of the past year, which it was my privilege as well as my bane to treat, I observed it in the lowlands of our county, on the highest hills, which dot its surface, on the rugged hills of Culpeper, along the meanderings of the smaller streams, as well as along the windings of the beautiful Rapidan. I observed it in the infant, in the woman of sixty years of age, in the adult, and in boys and girls just entering the arena of life, but by far the greater number of cases were between the ages sixteen and twenty-four years, and the greatest mortality between the eighteenth and twenty-second years of age. The sexes were about evenly divided. The epidemic began in July, and continued until the latter part of December, but the greater number of cases occurred during the months of September and of October.

I have neither a North Boston nor a Plymouth outbreak to record, but by observation I have found typhoid fever to be both contagious and infectious, caused by contaminated water, contaminated milk, contaminated vegetables, contaminated food, contaminated apartments, mainly sleeping apartments, and I have found flies to have been frequent carriers of this disease. I have also found that the dejections after having been thrown out and dried would frequently cause the disease. In one case the bacilli were carried by the wind for half a mile or more. Carelessness and want of cleanliness on the part of physicians and nurses are frequently responsible for an outbreak.

I have practised medicine in the Piedmont section of Virginia for the past twelve years, seeing the eruption of typhoid fever but rarely. During the past year, however, it was present in almost every patient. I saw it on the chest, on the abdomen, on the back, on the limbs—in fact, all over the body, even on the face. Therefore my deduction as to the eruption is that it is not present in every case, but during the epidemic of last year it was present in nearly every case, and much more abundant in crowded tenement houses. The hair came out in about one half of

[1] Read before the Medical Society of Virginia.

my patients. In patients suffering from relapses, transverse lines or ridges may be observed running across the finger nail, the number of lines being in proportion to the number of relapses or recrudescences. In one patient recovery was much retarded because of boils, which developed during the eighth week and lasted six weeks. They aggregated the colossal number of 300 and were distributed from the crown of his head to the soles of his feet.

For a variable time, ranging from ten days to three weeks, after the reception of the poison in the system and until its outward manifestation, the patients suffered from lassitude, languor and general malaise. The tongue appearances varied from a light furring to a leathery blackness, in which latter case it would peel off and become dry and glazed. A return to a moist condition marked convalescence. Old writers paid great attention to a quartette of symptoms, namely, nose-bleeding, diarrhea, iliac tenderness and meteorism. In not a single patient did I observe all of these symptoms. Epistaxis occurred in but two patients; looseness of the bowels in about one-half of the number, iliac tenderness in about one-third, while meteorism was present in most. In one of the worst cases that I have ever seen, lasting for more than three months, and followed by post-typhoid mania, none of the typical symptoms were present. In a patient who recently came under my observation the most marked tenderness was over the sigmoid flexure.

Beginning about the middle of the third, or the latter part of the second week, in adults, earlier in children, the most dangerous symptom, intestinal hemorrhage, is to be feared. In the present epidemic it varied in quantity from a few drops to quarts of blood, and the color varied from bright red to tarry black. One patient, a young man, actually bled to death and another patient, a young woman, under the care of a neighboring physician, showed signs of an internal hemorrhage, and at her death a perfect deluge of blood poured forth.

During this epidemic a case came under my care which illustrates our inability to foresee this dangerous symptom. The patient, a young woman, had had typhoid for three weeks, at the end of which time a recrudescence occurred. For four weeks more she went through all the stages of another attack. At the end of this time she showed every sign of convalescence, when a second recrudescence took place, again lasting for four weeks. At the end of the eleventh week her temperature became permanently subnormal. In her thirteenth week she began to convalesce slowly. One significant fact was that during these attacks she would pass masses of necrotic tissue in the stools. At times in this necrotic tissue there would be specks of blood, and at other times there would be an exhaustive hemorrhage. These hemorrhages ranged in quantity from drops to quarts and in color from a bright red to tarry black.

Deep seated ulceration I saw in three cases occurring in young girls. It manifested itself by deep-seated, burning pain in the right iliac region, quick pulse, anxious expression of the countenance, and prostration. But by far the most dangerous complication which can arise is perforation of the bowel. A young man had had typhoid fever for four weeks, but was still walking about. When all at once, he was seized with a severe pain in the abdomen and in the penis; there was a quick, almost imperceptible pulse, anxious expression, pinched features, peritonitis, collapse, a temperature of 109.9° F., and death.

Swelling of the parotid gland, I have observed in one case, which was in a marked relapse. The urine in the early stages is scant, and of high specific gravity; an increase in quantity and lowering of the specific gravity marks convalescence. Bronchitis was present in nearly every patient, and was accompanied by more or less cough. This was relieved by turning the patient frequently. Hypostatic congestion of the lungs was noted in a number of cases of young plethoric boys. It was usually bilateral. Pneumonia, both lobar and lobular, was not infrequent —right here permit me to advise the young practitioner not to rely on subjective symptoms, but to make a physical examination in every case. Laryngitis was found in one patient.

The respiration is increased in frequency during the fever, and during convalescence I have seen it fall to 12 for five or six days. When pneumonia does not exist, I have found that a spasmodic or jerking inspiration is a precursor of coma.

As is well known the pulse is increased in frequency. In a case which came under my care the pulse during the second week of the disease went up to 140, and remained there for three weeks unless controlled by remedial agents. A range from 90 to 120 is common, with a mean range of 100 for many cases. Dicrotism was present in a few cases. In one during convalescence, the pulse dropped to 54 and remained at this rate for over one week. I have found the sudden collapse in typhoid fever due to a myocarditis. I observed thrombosis in two cases. One in the right leg, and one in the left leg.

Pain in the head in the early stages is more or less acute. In some patients the action of the typhoid toxins is expended on the nervous system and the pain is so severe that it resembles meningitis, but on close observation it will be found that meningitis is an exceedingly rare complication. One patient, a young man, observed in 1899 was convalescing from typhoid fever when cerebrospinal meningitis developed, which rapidly proved fatal. Some cases ran the course of the disease without delirium. The delirium amounts only to incoherent answers to questions, or simply a wandering, while with some it is uncontrollable and requires restraint in bed. In one instance a young woman became wild during the first week, the delirium and fever lasted for ten

weeks, at the end of this time both fever and wild delirium left her and she developed post-typhoid insanity from which after some weeks she recovered. Subsultus tendinum was present in a few cases. I find that picking at the bed-clothes is vastly overestimated as a bad symptom. Muscular twitching is extremely common. In one case paralysis of both lower extremities developed. This improved gradually, the anterior tibial group of muscles was the last to react. The so-called typhoid spine of Gibney I have seen in only one case, that of a young woman who has always had some menstrual irregularity.

Three stages of fever were observed, namely, increment, fastigium and decrement. Roughly speaking, the first stage lasted a week; the second, two weeks, and the third, one week. The fever would usually rise, in a step-ladder fashion, for from five to ten days, having the morning fall and the evening rise, and rising higher on each succeeding day to be followed by the stages of decrement, which declined gradually as the patient advanced. In some cases the rise occurs in the morning; there also may be an ambiguous form of fever. The rise may take place morning, noon or night; the temperature may fall to normal, and perhaps during the same day it may rise to 104.5° F. In several cases observed by me the fever seemed to be due to an anemic condition or to nervous phenomena, improvement taking place readily as soon as the patients were allowed to go to the fresh air and take exercise. Sudden falls of temperature take place as the result of hemorrhage.

Mortality.—I lost six cases, as follows: One from perforation of the bowel; one from hemorrhage from the bowels; one from cerebrospinal meningitis; one from abortion; one, a whisky drinker; one from general nervous prostration.

Treatment.—Rest, both mental and physical, is the prime requisite. The patient, as soon as suspicious symptoms declare themselves, should be put to bed in a large, cool, airy room. In the early stages the room should be kept dark, and when convalescence sets in the sunlight should be admitted. The patient should be given repeated doses of calomel until the bowels are moved well. The hair cut close, clipped, or the head shaved, the patient should be made to sleep by such hypnotics as sodium bromide, chloral, a a. gr. x, trional, gr. x, or sulphonal in hot water and in some cases hypodermics of morphine. In some few cases I have found sulphate hyoscyamine in $^1/_{100}$ grain doses to act well. The ice-cap applied to the head will often produce quiet and refreshing sleep.

Reduction of Temperature.—In the early stages, or as late as the middle of the second week, I use cold tub-baths if there is no idiosyncrasy; in the latter case, I use warm water. If the temperature remain high, later in the disease, I find nothing to act better than an ice-bag along the spine, also sponging the patient with ice. An ice-cap to the head relieves the fever, prevents delirium and produces quiet sleep. Sponging with equal parts of water and alcohol fills a good indication. Coal-tar preparations in the reduction of fever I have long since discarded, as I am satisfied that I have done great harm with them.

Antiseptic Treatment.—Of all the antiseptics which I have used internally I have found Watson's chlorine mixture to be the best.

Tonics and Stimulants.—If I were called upon to discard all drugs save one, I would unhesitatingly choose strychnine. I give it in the early stages to prevent cardiac weakness. I give it in the later stages to prevent collapse, to hold my patient up and keep him from dying, and I give it during convalescence as a general tonic and to prevent paralytic troubles. I find that the doses usually given are too small. I have given $^1/_{20}$ grain of nitrate of strychnine every three hours for twenty-one days, to a patient in great danger from cardiac failure, and whenever the dose was lessened or the time lengthened I found great weakness. Nitroglycerin is a quick stimulant to a failing heart, but not permanent like strychnine. Digitalin in $^1/_{60}$ grain doses I found of value in giving the heart rest. A young woman whose heart was beating 140 times a minute, and which kept at that rate unless held down, would be quieted by digitalin and become strong. Turpentine I still find a remedy of great utility in tympanites. In the early stages light wines act well, but later on nothing will take the place of good rye whisky or French brandy. In cases in which neither one can be borne by the stomach, recourse must be had to champagne.

Food.—From the first suspicion of fever until ten or twelve days after all fever has disappeared the diet should be liquid. Milk is one of the most important articles of diet. Care should be taken to see that it is properly digested. If not digested a mixture of acid. hydrochl. dil. and pepsin should be given. Next to milk I find albumin water or raw eggs good. The various animal broths are used with success. In some cases I have found my patients well, but each day there was some rise of fever, the tongue was clean, the abdominal tenderness gone, the appetite and digestion good. In such cases I have allowed my patients to get up and cautiously allowed them solid food, without any unpleasant effects. In connection with food is the frequent and free use of water and ice. Water should be given at regular intervals without the solicitation of the patient.

Treatment of Complications.—These should be treated as they arise, as follows: Hemorrhage, for which my sheet anchor is opium in some of its forms. Tannigen I find good. Injection of water medicated with witch hazel often seem to help. Perforation belongs to the domain of surgery.

Prof. Edmund B. Wilson, of Columbia University, delivered the annual address in Medicine at Yale University, June 25, on "The Higher Claims of Minute Search in Biology and Medicine."

A CASE OF LOBAR PNEUMONIA WITH HYPERPYREXIA; RECOVERY.

BY WM. R. WILLIAMS, M.D.,
OF NEW YORK.

THE rarity of cases of pneumonia with very high temperature at other times than just before death and the difficulty of finding reports of those that do occur perhaps excuse the publication of this note in these columns.

This patient was a well-nourished Italian, twenty-five years of age, who was in the Hudson Street Hospital under my care and later under that of Dr. Conner. He could speak no English so that his previous history remained unfathomable. He was admitted on December 7, 1900, on what was probably the second day of the pneumonia. He had been ailing for four days, but on the day before admission he had a chill and stayed in bed. Throughout the disease the tongue was rather moist and but moderately coated, the stomach behaved very well, although once he vomited after taking milk; constipation was constant. There was severe pain in the left side of the chest upon breathing and coughing, the sputum was rusty and very tenacious. The heart action was much accelerated, but of such force that under stimulation the pulse at no time became alarming. Delirium was pretty constant at night and was present to a moderate degree during the day also. It ceased altogether on the ninth day when the temperature fell.

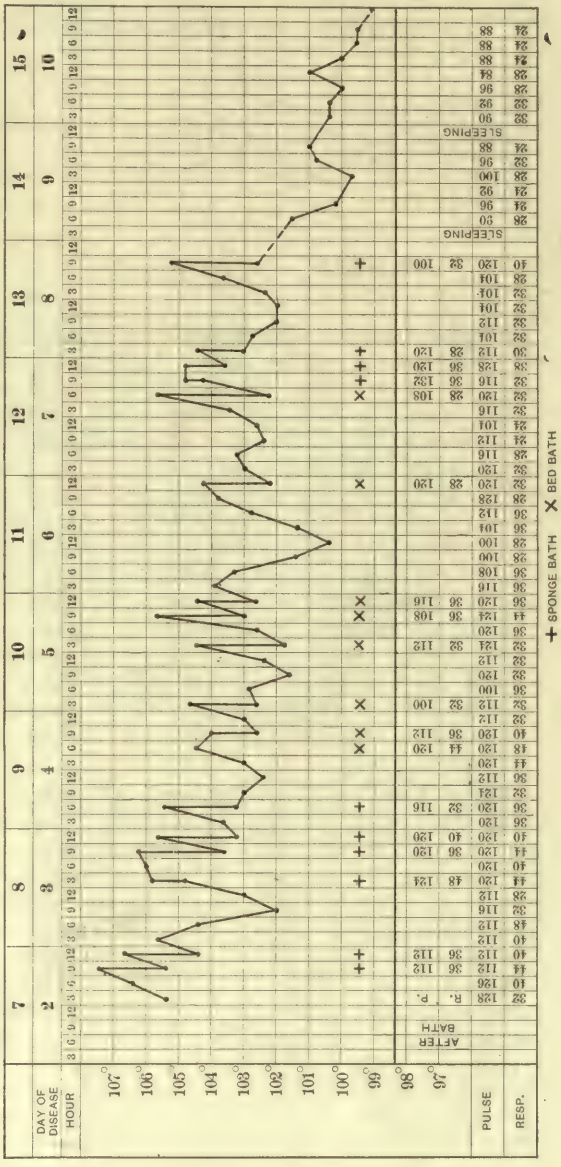
The temperature was taken in the rectum by means of a carefully tested thermometer and there seems to be no reason to doubt the accuracy of the record. The highest point was reached on the second day, 107.4° F. The accompanying chart shows clearly its subsequent meanderings and final subsidence. This chart shows also the respiratory and pulse-rates both before and after the baths.

The urine amounted to from thirty to forty ounces daily, was of a specific gravity of from 1,014 to 1,025. Upon admission it contained 20 per cent. by volume of albumin. This decreased slowly to 10 per cent. on the eighth day, and to a trace of albumin on the twelfth day. Many casts, hyaline and granular, were found during the continuance of the fever and for weeks thereafter. On the twenty-eighth day the urine was free from albumin for the first time and remained normal afterward.

The physical signs were the typical signs of consolidation and of fibrinous pleurisy over the whole of the left lower lobe. The conjunctivæ were distinctly yellowish, but the jaundice was not noticeable elsewhere. During the first two or three days the mucous membrane of lips and mouth was a little cyanotic, but after this the color was good.

From this sketch of the symptoms it will be seen that were it not for the records on the temperature chart the case would not have seemed an unusually grave one, aside from the marked urinary changes.

The treatment besides stimulation with whiskey and strychnine, and nervous sedatives for the delirium and sleeplessness (trional, codeine and morphine), consisted of some form of bathing. Because of our inability to explain to the patient the nature and object of tub-bathing, it was thought inadvisable to use this method. From the fourth to the seventh days inclusive, bed-baths were used. The temperature of the water was 50° F. The bath lasted for ten minutes.



The after-bath temperature and rates of pulse and respiration were taken half an hour after the bath. Before and after the above days the baths consisted of sponging for ten minutes with iced alcohol.

A glance at the chart will show that the temperature rose after the baths at 3 p. m. on the third day, and 9 p. m. on the seventh day, and that it was unchanged after the 6 p. m. bath on the fourth day. Yet, on the whole, the general result of bathing was quite satisfactory.

Notes of other cases of hyperpyrexia in this disease are rather rare in the literature. Fatal cases are reported with high temperatures of from 108° to 110° F. just before death.

Of cases that recovered are one with a temperature of 107° F. with double pneumonia[1]; one of 107.5° F. on the fifth day in a patient sixteen years old[2]; one of 108.4° F. in a boy of eighteen years with jaundice and a double pneumonia[3]; one of 109° F. in a child of three years[4]; one of 109.2° F. in a child of five years[5]; and one of 110° F. in a patient twenty years old just before the crisis[2].

MEDICAL PROGRESS.

Iodophilia in the Diagnosis of Suppuration and Pneumonia.—The term iodophilia is coined by T. DUNHAM (*Boston Med. and Surg. Journ.*, June 13, 1901) to designate a peculiar blood reaction which occurs in pneumonia before diagnosis can be made by physical signs, as well as in progressive suppurations. The reaction in question is a peculiar pink or red staining of polymorphonuclear neutrophiles when a dried blood smear is mounted in a syrupy mixture containing potassium iodide and iodine in solution. In so-called tuberculous abscess the reaction is absent. Other conditions in which it is present, as grave anemias and leucemia, are not likely to be confounded with suppuration or pneumonia in which two conditions the reaction is of diagnostic value.

Blister Test in Constitutional Diseases.—ROGER and JOSUÉ (*La Méd. Moderne*, May 8, 1901) report the existence of a definite relationship between the character of the cellular contents of a bulla artificially produced and a variety of infectious diseases. In normal man one finds among the cells which float in the serous contents of the blister, 25 per cent. of eosinophiles. In persons suffering from infectious maladies these cells are present in much smaller numbers or are wholly wanting. In proportion to the severity of the infection is the hematopoietic system impressed, with the result named. The blister test is shown to hold good in cases of erysipelas, mumps, acute tonsillitis, ophthalmic zona, bronchopneumonia and tuberculosis.

Lobar Localization of Hepatic Function: Its Relation to Abscess Formation.—FRANTZ-GLENARD (*La Méd. Moderne*, May 1, 1901) finds that water injected into the liver by means of the portal vein or hepatic duct does not cause a uniform swelling of the liver, but produces an enlargement and hardening of one lobe while the neighboring lobe remains flaccid. This illustrates an independence of lobar function which must be borne in mind when clinically palpating the diseased liver. Physiologically there are two separate currents within the portal vein: one current consists of blood from the superior mesenteric vein, the other of blood from the splenic and inferior mesenteric, and, while substances injected into the radicles of the superior mesenteric invariably reach the right lobe of the liver, similar injections in the territory of the inferior mesenteric find their way into the left lobe. Autopsy findings agree with these experimental findings. Abscess of the right lobe of the liver due to portal infection may always be traced to intestinal ulceration in the superior mesenteric region; if the left lobe be involved the source of infection lies in the descending colon, sigmoid or rectum.

Intrapelvic Infravaginal Perineorrhaphy.—Plastic operations that deal merely with the "perineal body" are only of cosmetic interest, the superficial muscles which are here attached being too delicate and not properly situated to give any real support to the pelvic floor. As the potential elements of the true pelvic floor of the female, namely, the levator ani muscle and its associated layers of fascia, lie within the pelvic cavity and at least 2.5 centimeters from the skin, they must be approached for proper repair from within the pelvic lumen and beneath the vaginal posterior and lateral walls. GOLDSPOHN (*Am. Jour. of Obstet.* June, 1901) accomplishes this without loss of tissue by first detaching the posterior and lateral vaginal walls for a distance of from 6 to 8 centimeters in the medium line and about half way up on the sides. The two opposing lateral portions of the deep pelvic fascia and levator ani are then by suture brought into direct contact in the medium line in front of the rectum and beneath the vagina; the flap of posterior vaginal wall now lies spontaneously adjusted into longitudinal folds upon the bridge which has been constructed for it. In Emmet's operation, with which this may be compared, there is approximation, but not actual contact of the deep lateral tissues.

Remote Results of Tuberculin Treatment.—CAILLAUD (*La Méd. Moderne*, May 28, 1901), reports the results of tuberculin treatment in five cases of pulmonary terberculosis and two cases of tuberculosis of bone. These cases were treated with the second toxin, "TR," early in 1898, and in both cases of osseous disease satisfactory results were obtained, which have persisted three years after treatment. In the pulmonary cases the report is negative. Caillaud urges the importance of trying tuberculin cautiously in cases of tubercular arthritis before resorting to mutilating operations.

Treatment of Insanity by Rest in Bed.—Russian writers have objected to the treatment on the ground that it leads to constipation and loss of weight, facilitates masturbation and makes it difficult to get patients to resume ordinary life. WIZEL, however, is a strong advocate of

the method (*Ann. Méd. Psych.*, Paris, 1901. No. 2). Many of his patients have gained in weight. Constipation has not been increased. Patients are permitted to rise for their meals and to go to the closet. Constant observation is practised, but no restraint. Separate wards are used for noisy and quiet cases. Since introducing this treatment Wizel finds his asylum quieter and more like an ordinary hospital.

The Presystolic Murmur.—HUGH WALSHAM (*Lancet*, May 18, 1901) shows by means of the Roentgen rays that the presystolic murmur of mitral stenosis is synchronous with the presystolic thrill of that disease. If the hand be placed over the precordial region at the point of the maximum intensity of the thrill, we find that the thrill corresponds to the advance of the left border of the shadow of the heart, to the left, and ends abruptly with the retreat of the shadow to the median line. Or that the thrill is obviously presystolic in rhythm and ends with systole. If, at the same time, the stethoscope is placed upon the heart, it will be found that the murmur begins at the moment when the shadow of the left ventricle is advancing to the left—that is, during auricular systole—and ends abruptly when the shadow retreats toward the medium line, that is, with ventricular systole.

Flies and the Science of Scavenging.—G. V. POORE (*Lancet*, May 18, 1901), advises that every means should be taken to dispose of human and horse excreta, as it is in these materials that the female fly lays her eggs. The best method is to bury the excreta in long shallow furrows, rather than in deep trenches, which take too long a time to dig and thus necessarily increase the cost of the work. The author is convinced that enteric fever is caused by the carrying of the germ from the excreta to the human subjects by flies. Cow dung should be stacked in piles and then covered with earth, so that the female fly cannot deposit her eggs in it. As each fly lays about 120 eggs at a time it is reasonable to suppose that in a hot summer she will breed in all, over 25,000,000 descendants.

Sterilizing Soft Catheters.—H. T. HERRING (*Brit. Med. Jour.*, May 25, 1901), describes a new and original method of sterilizing soft catheters. A series of metal tubes are connected with a flask which has been filled with paraffin and water. On heating the contents of the flask the steam and paraffin pass up into the tubes containing the catheters and coat them with paraffin. Bacteriologic examinations show that this method is highly efficacious. These tubes are plugged with sterilized corks and are ready for use when needed. It takes about twenty minutes to sterilize a dozen catheters.

Erythema Multiforme and Vaccination.—NORMAN WALKER (*Brit. Med. Jour.*, May 18, 1901), says that many cases of vaccinations are followed by an erythema even after four weeks, in which it is difficult to distinguish it from erythema iris or erythema multiforme. The hands, face and legs are covered with a bullous eruption in some cases. All these cases, which came under the author's observation, have been vaccinated with glycerinated lymph, which makes the writer wonder if the erythema may be due to some toxic substance introduced with the vaccinia virus. Gilchrist of Baltimore thinks this is the best explanation. The course of the erythema was uneventful and the eruption very rapidly disappeared.

Malignant Diseases.—After carefully analyzing 5,000 cases of death from malignant diseases, E. N. NASON (*Brit. Med. Jour.*, May 18, 1901), says that all predisposing causes resolve themselves into conditions in which the resisting powers of the individual have in all probability been reduced or destroyed. When this condition exists it is the time for the invasion of the parasitic organisms, if there be such organisms. Granting the existence of such germs, they must enter the points of inoculation by direct absorption, by the intestinal tract, by way of the respiratory tract or by direct inoculation through skin abrasions, or by bites of blood-sucking insects.

The Nasopharyngeal Origin of Goiter.—From the study of 209 cases of goiter, H. DU FOUGERAY (*Le Progrès Médical*, May 25, 1901) believes that chronic catarrh of the nasopharynx is probably one of the causative factors of goiter. By proper treatment of this region, the goiter disappeared in 52 cases, diminished notably in 133, and was only slightly affected in 24. One of the cases presented exophthalmos, but a slow pulse and no definite sign of Grave's disease; and both exophthalmos and goiter yielded to intranasal treatment. In two cases of true exophthalmic goiter, great benefit was obtained, but the results are too recent to be conclusive. It is a fact that rhinopharyngitis is the rule among goitrous patients, and lately it has been shown that the thyroid and pharyngeal veins anastomose and have but few valves, so it may be possible that a congestion of the pharynx may be such as to relieve itself on the thyroid system, and so produce there a hyperemia, and then a goiter. The author's routine treatment has been to paint the oropharynx three times a day with 10 per cent. mentholated oil, to spray the nose with the same oil five or six times a day, and to cauterize the affected parts of the nasopharynx with a 50 per cent. solution of chromic acid.

Vaginal Hysterectomy.— A. DÖDERLEIN (*Archiv f. Gynäkol.*, B. 63, H. 2 and 3) describes a new modification of this operation which consists of the following steps. After the insertion of two lateral and one posterior vaginal retractor the cervix is seized by two strong volcella at its right and left margins, drawn strongly down and divulsed. With scissors in the median line posteriorly the posterior lip of the cervix and the vaginal wall are divided into the cul-de-sac of Douglas. When this is divided in the median line behind. The cervix is

reached, extrapertioneally the uterine body is meanwhile drawn steadily forward and the lips of the uterine wound farther and farther apart. When finally the fundus is reached and cut through the organ lies outside the vulva and opened up somewhat like a fan. The anterior uterine, cervical and vaginal walls are now divided *seriatim* until the base of the bladder is reached. The halves of the organ are now stripped of peritoneum and the attachments still left within the pelvis are tied and cut through. The wound is then closed by some of the well-known steps.

Myomectomy During Pregnancy; Delivery at Term.—Myomata of the pregnant uterus are divisible into three classes: (*a*) Pedunculated myomata not apt to interfere with pregnancy or delivery and not calling for surgical interference; (*b*) subperitoneal and interstitial tumors of the body, removal of which is liable to be followed by abortion; (*c*) sessile or pedunculated tumors which are so situated that interference with delivery is inevitable. The advocacy of hysterectomy when surgical interference is called for is considered by J. D. EMMET (*Am. Gyn. and Obstet. Journ.*, June, 1901) to be founded on the erroneous belief that myomectomy is nearly always followed by abortion. The author removed in one case nine sessile myomata, one of which was deeply interstitial. Pregnancy continued uneventfully to term.

Cancer of the Lower Lip.—A. STIEDA (*Archiv f. klin Chir.*, B. 63, H. 3) states that all operations for cancer must involve not only a removal of the cancer itself, but also of the efferent lymph-channels and glands. The area which these cover is roughly bounded on each side by the body of the lower jaw and behind by the hyoid bone and in front by the symphysis. The incision which exposes this large field begins practically at the angle of the lower jaw, follows the body forward to the symphysis and then curves backward along the body on the other side till the angle there is reached. The large horseshoe-shaped flap thus made is folded backward along its base and the two submaxillary triangles and the submental space are freely exposed for cleaning out.

Treatment of Chorea Gravidarum.—Physical and mental calm are regarded by OUI (*Jour. de Méd. de Paris*, June 16, 1901) as of primary importance. If necessary the patient should be kept in bed. Although Vinay counsels the use of large doses of antipyrin, its action on the kidneys contra-indicates its use in pregnant women in whom renal integrity is indispensable. Bromide of potassium, zinc oxide and valerian have given very variable results. Chloral is highly recommended, its administration being conducted by Oui according to the rule of Pinard, who prescribes sufficient doses to keep the patient asleep almost continually, arousing her only for meals.

Skiagraphy in Surgery.—J. RUDIS-JICINSKY (*Annals of Surgery*, 1901, No. 6) states that as the technic of making skiagraphs improves, the value of its resources in surgery is increased, the fields of its usefulness and application widen and its errors and false interpretations become less numerous. The Roentgen-ray may be used with increasing safety and accuracy. It reveals in proper hands more than examination under ether, without the danger and discomforts of an anesthetization. It often does away with the necessity of any manipulation whatever. The duration of the exposure is usually a matter of experiment and experience. After five negative skiagraphs made by an exposure of several minutes, he succeeded in demonstrating the gallstones sought by making the exposure only fifty seconds. A change of view-point is also desirable when the picture resulting is not favorable. A series of views must also often be had from various points in order to give all the necessary information. After a little experience, the shadows will show not only the position of bones, but also their pathological condition. The author then cites examples of old dislocation of the hip, diagnosed as coxalgia, of old blood-clot under the parietal bone without definite clinical diagnosis and of early spondylitis, all made definitely correct by the use of the X-ray.

Value of Calcium Carbide in Inoperable Uterine Carcinoma.—It is believed by I. C. CHASE (*Jour. Am. Med. Assoc.*, June 22, 1901) that many inaccurate statements have found their way into recent literature on the subject of calcium carbide. In contact with water this substance is violently disintegrated, liberating acetylene according to the formula $CaC_2+H_2O=CaO+C_2H_2$. Chase finds that acetylene has no specific annihilative action on carcinomatous cells; it has no escharotic effect and no bactericidal action on pathogenic bacteria or bacteria of putrefaction. The principal action of calcium carbide is due to the quicklime liberated. But if a caustic is desired lime is not a rational selection, because of its superficial action, the character of the necrosis and the tendency to promote hemorrhage. The amount of heat evolved may be sufficient to slighty cauterize the tissues; the heat of actual cautery, however, gives firmer cicatrices with better resistance to carcinomatous invasion.

A Modified Murphy Button.—E. P. PAYR (*Deutsche Zeitschr. f. Chir.*, B., 59, H. 3 and 4) in a contribution on the technic of various abdominal operations describes a feature of a Murphy button which is briefly a great elongation of the male tube. The advantages of this tube in operations which permit it to be used are that it forms a drain and irrigation channel and a protection to the outer dressings. The operations for which it is best adapted are resections of the rectum and colostomies. In the resection of the rectum the proximal stump of sigmoid colon is attached to the male segment and the anal portion to the female. When the two are united the long tube projects outward in the axis of the bowel and beyond the level of the perineal plane. Suitable drains and dressing are applied around it

and ordinarily remain perfectly clear of fecal matter. The same purpose is carried out more fully by attaching a rubber hose over the end of the tube which can be carried into a receptacle containing an antiseptic, beneath the bed. If the feces are kept fluid by small amounts of saline purgatives, they will drain away steadily. Gentle irrigations may be practised through this tube-system also. In the colostomies, especially the inguinal, whether lateral or after transverse division of the bowel; the male part is put into the bowel and the female placed upon it with only the transversalis fascia and peritoneum between.

Pseudo-Myxedema Due to Testicular Distrophy.—A man, thirty-six years of age, who gave a syphilitic history, and who during five years experienced lassitude, weakness of the lower extremities, mental dulness and sexual impotence was examined by DALCHÉ *(La Semaine Méd.,* June 12, 1901). The legs, abdomen and face were the seat of a hard infiltration resembling myxedema. The thyroid was of normal size; the testicles were markedly atrophied. There was a total loss of vision in the left eye, due to choroiditis. Mercury and iodide of potassium gave no relief. Testicular extract was then resorted to and in a few days the subcutaneous infiltration disappeared and the patient's mental and sexual potency returned.

Surgery for Typhoid Fever.—T. J. MACLAGAN (*Brit. Med. Jour.,* June 15, 1901) says that there are a certain series of typhoid-fever patients in whom during the third and fourth week of the disease the intestinal ulcers begin to cast off their sloughs. These are usually small and pass into the cecum and along the large intestines and are voided without difficulty. Occasionally, however, the sloughs are individually large or through weakness in the bowel-wall collect in masses which are retained in the cecum. Here as the decomposition goes on it leads to toxemia by absorption and to a low grade of obstruction by its mass and the increased paresis of the gut-wall incident upon the accumulation of the gases produced. When such a condition is not alleviated by medical means the author commends resort to surgical emptying of the loaded cecum. His contention, although not based on actual experience, points to the probability that this will be, like intestinal perforation in typhoid fever, a fixed indication for surgical treatment, and interference in properly selected cases at the fitting time will prove another fertile means of saving life.

Nauheim Baths.—The value of the Nauheim treatment, especially in cardiac troubles, is discussed by H. N. HEINEMAN *(Med. Rec.,* June 22, 1901) who believes that in selected cases much benefit can be given. The important elements in the treatment are as follows: The warmth and the fact that it is a natural warmth, avoiding any injurious artificial application of heat by which important elements may be dissipated; the presence of alkaline salts and metals and also rarer elements the value of which is unknown; the large quantity of carbolic-acid gas held in active form; and, finally, a certain quantity of electromagnetism which these waters have in common with certain other springs. When patients with weak hearts are placed in a bath at 33.5° C. to 35 C. they first experience a feeling of oppression over the sternum, never alarming, and this is usually followed by a slowing of the pulse and respirations after the first hurried respirations have subsided. At the beginning the baths are kept up only four to six minutes, the time being increased in some cases to twenty minutes. To obtain the best results the Schott methods of exercise should be combined with the baths and this is now usually done at Nauheim. In addition, various cardiac disorders, such as myocarditis and fatty heart, and all forms of loss of compensation, numerous other chronic disturbances, such as nervous troubles, rheumatism, gout and inflammatory exudates, may be remarkably improved by this method of treatment.

Symmetrical Lipomata.—FÈRÉ and M. FRANCILLON (*Revue de Chirurgie,* 1901, No. 61) state that symmetrically occurring fatty tumors are equally common in people free from pathological taint, as in those afflicted with arthritis, albuminuria, alcoholism, rheumatism and cancer. They are comparatively rare in the nervous diseases, but have been reported in the insane, epileptic, tabetic, sciatic, general paralytic and other classes of the nervously afflicted. As to the pathogenesis of these fatty masses in multiple and symmetrical occurrence we are unfortunately ignorant, although a number of theories are extant, each having its advocates and its cases to support it. The chief theories recognize a lipomatous diathesis, or a vascular hyperplasia with a formation of new tissue, especially fat, or some connection between thyroid hyper- or subactivity, or a connection with lymphatic-gland or vessel changes, or, finally nervous trophic influences.

"Fourth Disease."—J. J. WEAVER *(Dublin Med. Sc.,* June, 1901), reports a series of cases of an affection which has been provisionally called "fourth disease," because of its clinical resemblance to, but distinctness from measles, scarlet fever and German measles. The closest resemblance is with German measles, the principal point of distinction being the rash. While the rash of German measles is always patchy at some stage, that of "fourth disease" is uniform, finely punctate, and practically indistinguishable from scarlet fever. The rash of "fourth disease" appears first around the mouth; the temperature rarely exceeds 100° F. and the pulse is not much slight or absent, there is little feeling of accelerated; moreover, the throat symptoms are illness and no loss of appetite. As in German measles, the incubation period in "fourth disease" is from nine to twenty-one days; in both affections the eruption is the first symptom. Posterior cervical glandular enlargement is absent in "fourth disease," desquamation is rare, and sneezing, coryza and cough do not occur.

Abolition of the Pupillary Reflex and its Re-

lation to Syphilis.—The permanent abolition of the pupillary reaction to light, provided it is not associated with a lesion of the globe of the optic nerve or of the third cranial nerve, is almost pathognomonic of hereditary or acquired syphilis. BABINSKI and CHARPENTIER (*La Méd. Moderne,* May 21, 1901) have made numerous observations in confirmation of this view. A patient in whom this pupillary sign appears is a candidate for tabes dorsalis, meningo-encephalitis or syphilitic affection of the brain or cord. As the sign may be unaccompanied by any symptom, it should be systematically sought for, and where it exists specific treatment should be begun at once.

THERAPEUTIC HINTS.

Infant Feeding.—The rapid cooling of milk with proper aeration, following strict cleanliness in its production, are the essentials for pure milk. Such milk sent from this country to the Paris Exposition was sold there as fresh milk. Chemical preservatives and sterilization are harmful, but heating to 170° F. will destroy most of the bacteria without hurting the milk. At 50°-60° F., nine-tenths of the butter-fat rises to the top of a bottle of milk in twelve to twenty-four hours, so that the upper nine ounces of a quart bottle will contain all the cream, and the percentage of fat to proteids will be three to one. This is about the proportion in human milk, so it is only necessary to dilute this and add sugar to approximate the proportions in human milk. A milk containing about 4 per cent. of fat will give in the first nine ounces 12 per cent. of fat, 4 per cent. of sugar and 4 per cent. of proteids. This, diluted three times, gives fat 4 and proteids 1, and by the addition of one part of sugar to each twenty of the dilution, makes the sugar 6, about the composition of human milk. A milk containing 3 per cent. of fat yields in its upper nine ounces, 9 of fat and 3 of proteid, while a 5 per cent. milk gives 15 fat and about 4½ proteid. The proteid of cow's milk, however, makes hard coagula, not easily penetrated by the digestive fluids, while the curd of woman's milk is soft. But cereal decoctions have been found to make the curd of cow's milk soft, so the author uses for dilution a dextrinized wheat, barley, or oatmeal gruel. He dextrinizes it by adding diastase or a malt extract made by soaking a tablespoonful of malt barley grains over night in two tablespoonfuls of water in a refrigerator.—H. D. CHAPIN (*American Journal of Obstetrics,* May, 1901).

Puerperal Sepsis.—Thorough disinfection of the whole genital canal should invariably precede other treatment. HIRST administers a 1-2,000 bichloride intra-uterine douche, then goes over the whole uterine surface with the curette and placental forceps, and then gives another intra-uterine douche. If the womb is flabby and large so that drainage is poor, he packs with iodoform gauze. Any local areas of inflammation in the vagina should be touched with silver nitrate, 10 per cent. If the symptoms continue, douches of plain water should be given several times a day. The patient must be given as much easily digestible food, chiefly milk, as she can assimilate, and much alcohol. Digitalis, if the pulse is above 110, and strychnine, or, in emergency, ammonium carbonate by the bowel, or nitroglycerin by hypodermic, may be required. Inhalations of oxygen may be useful. Absolute rest and freedom from mental and physical disturbances must be insisted upon. For two years the author has used nuclein as a routine part of his treatment to promote hyperleucocytosis. Recently hypodermatoclysis and saline injections have given good results; the best fluid for this purpose is calcium chloride, gm. 0.1 (gr. iss), potassium chloride, gm. 0.75 (gr. xiss), and normal salt solution, 1,000 c.c. (34 oz.). The infection may be so severe as to demand laparotomy with removal of uterus, tubes, or intraperitoneal abscesses.—B. C. HIRST in "Text-Book of Obstetrics."

Pneumothorax.—If intensely severe symptoms attend the perforation, a hypodermic of morphine should be given immediately. It relieves the mental distress, checks cough, and lessens the dyspnea. If there are marked signs of shock, and cardiac failure threatens, ether should be injected hypodermically at intervals. The movements of the affected side may be restrained, and overdistention prevented by broad adhesive straps extending beyond the median line both before and behind. The engorgement of the right side of the heart requires its own special treatment. It sometimes happens that severe dyspnea disappears spontaneously on the occurrence of pneumothorax. When a valvular opening in the lung allows the pleural cavity to so fill with air that the lung is compressed. A cannula should be inserted in an intercostal space and left till the lung is healed. Cases of tubercular pyopneumothorax do badly after free incision. A good treatment for these cases is to place patient on the back at the edge of the bed, and to insert two hollow needles with rubber tubes attached, one in the anterior chest and the other in the posterior. The anterior tube comes from a large bottle of warm boric-acid solution prepared with sterile water, and the other tube is connected with an aspirator or drains into a basin on the floor. The fluid runs from the chest and is replaced by the boric solution. When the stream runs quite clear, the anterior needle is withdrawn, and as much as possible of the remaining fluid removed. If the accumulation of air causes trouble, it may be removed in the same way as fluid, by aspiration. Ordinary pyopneumothorax requires the same treatment as empyema.—FOWLER AND GODLEE in "Diseases of the Lungs."

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, JULY 6, 1901.

PARASITES FROM THE PHILIPPINES.

SINCE acquiring the Philippines we have been realizing by degrees something of the heterogeneous nature of our new possessions. With our tendency to "want the earth, and get as much as we can hold," we discover, as did Mrs. Stetson's Neolithic man, that

"We're going to have diseases and accomplishments and sins."

A circular on Tropical Diseases coming from the printing office of the Chief Surgeon of the Headquarters Division of the Philippines lies before us. It is one of a series prepared to place in the hands of physicians when they arrive in these islands in order to enable those who have had no experience with the diseases of the tropics to aid in the diagnosis of the common maladies as well as to prevent their epidemic spread.

This first issue is replete with parasites, those of the animal kingdom alone being described. Certainly the struggle for existence must be keen in the Philippines if so many parasites are found as are here described. Amœba dysenteriæ, amœba coli, balantidium coli, three flagellate infusoria, undetermined, tænia solium, tænia saginata, tænia echinococcus, ascaris lumbricoides, oxyuris vermicularis, trichocephalus dispar, trichina spiralis, filaria sanguinis hominis, anchylostoma duodenale, strongyloides intestinalis, calliphora vomitoria, anthomyia canicularis, hirudo and paragonimus Westermanii are among those enumerated in this preliminary report.

To realize that these parasites are extremely common and very liable to infect foreign soldiers, especially if they fall into the careless and slovenly habits so readily acquired in the tropics, is a matter of the greatest importance to the physicians of the army. Familiarity with the diseases they will certainly acquire by disastrous experience if they are not forewarned, and more than one tropical malady will come to the United States if we are not forearmed; but the dissemination of such circulars as these promise to be, will prove most efficacious in diagnosing the diseases and prevent them from spreading.

THE SURGICAL TREATMENT OF AMEBIC COLITIS.

FEW, if any, diseases are more obstinate in their resistance to treatment which is at times apparently curative than amebic dysentery. In the early stages, before the amebæ have secured a firm foothold in the deeper layers of the intestine, and before extensive ulceration has occurred, irrigations may both arrest their growth and lead to permanent recovery. On the other hand, improvement or apparent cure is often only temporary, and repeated and protracted treatment may fail to produce any lasting effect. There is good reason to suppose that if, in these unyielding cases, the intestine could be kept absolutely at rest, free from all irritation, stimulating, antiseptic, and astringent irrigations would be far more effectual. This principle has been applied in the treatment of other inflammatory and ulcerative processes in the large intestine, but apparently has only recently been employed in amebic colitis.

Murray (*Annals of Surgery*, May, 1901) obtained a partial success in a most obstinate case by the formation of an incomplete artificial anus. The partial rest secured to the colon by this procedure, with irrigation from the colostomy opening downward with various solutions, of which silver nitrate seemed most efficient, caused marked improvement. Before the operation the effect of irrigation had been extremely transitory. While under observation after the colostomy the amebæ appeared at times in small numbers, but recovery was

sufficient to allow the patient to work for the first time in over two years. Six months later he was found still able to work, with the colostomy wound nearly healed, and the movements numbering two or three a day but always containing mucus. The writer acknowledges the incompleteness of the method employed and advocates for the treatment in future of chronic cases of amebic colitis, the formation of a complete artificial anus followed by irrigation. He considers as suitable cases for this procedure those which fail to yield to medical treatment within four months.

Judging by the results obtained with other forms of ulceration and by the partial cure following the incomplete operation in Murray's case, it seems not unreasonable to suppose that even such an intractable affection as amebic colitis may yield to a complete colostomy. The artificial anus should be left open until, as the writer suggests, no amebæ are found in the irrigating fluid, and examination of the lower portion of the bowel through the anus and the ascending colon through the colostomy wound, by means of Kelly's long rectal speculum, fails to disclose the presence of ulcers. In view of the progressive character of the disease, leading to a fatal result, it appears perfectly justifiable to expose the patient to the danger incurred by the operation. The number of cases of amebic colitis in this country is likely to increase with the acquisition of colonies where it is prevalent, and the importance of what bids fair to lead to a cure will correspondingly advance.

HYPODERMOCLYSIS IN THE TREATMENT OF PNEUMONIA.

NEARLY nine years ago the MEDICAL NEWS published an editorial article by the present writer upon the treatment of pneumonia, embodying what seemed to be the most advanced position of that day (August 20, 1892). In that article which strongly urged the discriminating use of venesection and the timely use of oxygen is likewise to be found the following: "Subcutaneous infusion (hypodermatoclysis) of saline solutions, as practised by Dr. F. P. Henry of Philadelphia, is unquestionably useful, probably by helping to maintain the fluidity of the blood in the same manner as the internal administration of ammonium salts, and by washing out noxious matters."

As the question of priority in this method of treatment has recently been agitating some medical writers and medical journals, it may be well to give it further consideration. As our statement above quoted shows, Dr. F. P. Henry of Philadelphia had for some years previous to that time treated cases of acute lobar pneumonia by using, among other measures, subcutaneous infusion of physiologic salt solution, and the method was presumably so well known to all readers that it was not considered necessary at that late day to call attention to its novelty or to describe the process.

As a matter of historic fact Dr. Henry's first case was treated at the Philadelphia Hospital in the year 1889. His first publication on the subject is contained in a footnote in Hare's System of Practical Therapeutics, first edition, 1892, volume 2, page 290, in the course of a chapter on typhoid fever which he contributed to that work. He says, "The surest method of conveying water to the tissues is by subcutaneous injection of (deci-) normal saline solution—a solution of common salt of the strength of fifty grains to a pint. About three years ago a number of cases of pneumonia at the Philadelphia Hospital were treated by the writer in this manner and with excellent results, both as regards palliation and cure." This and our own reference certainly constitute sufficient publication, even if nothing further had been said upon the subject from that day to this to establish Dr. Henry beyond doubt as the originator of the method, and to render it incumbent upon any further worker in the field to refer to Dr. Henry's observations.

However, there have been additional publications made. At the meeting of the Association of American Physicians in 1894, Dr. Beverley Robinson of New York read a paper on "The Treatment of Pneumonia," in the course of which he said, "In a late number of the *Virginia Medical Monthly*, Dr. Cunningham of Ensley, Alabama, contributed a very valuable paper in which he writes that he employed hypodermoclysis of saline solution daily in just such cases, with the object of preventing cardiac failure which, he thinks, may be due to antemortem clot." In the discussion of Dr. Robinson's paper, Dr. James C. Wilson of Philadelphia remarked, "In regard to the intravenous or hypodermatic administration of large quantities of sterilized salt solution, alluded to by Dr. Robinson, I would like to call the attention of the Association to the fact that this method has been practised to a consider-

able extent in the wards of the Philadelphia Hospital by Dr. Henry, and in cases of this kind, with very satisfactory results." This brings Dr. Cunningham into the field as another worker in the same line, apparently independent of Dr. Henry, and certainly with priority over any one subsequent to Dr. Henry.

In the *Philadelphia Polyclinic* for July 20, 1898, the present writer, in the course of a signed editorial on "The Uses of Physiologic Salt Solution, or Artificial Serum," says, "A perusal of current literature will show how much the use of physiologic salt solution is extending. It is introduced in urgent cases by intravenous injection, in less urgent cases by subcutaneous infusion or hypodermoclysis. In toxemias, in which class of cases, for example, delirium tremens and pneumonia both find place, preliminary or coincident venesection may usefully be made. We have seen recovery take place in doubtful cases under this form of treatment. In some cases the injection, after a preliminary irrigation, of a pint or a quart of warm saline solution into the colon, by means of a large rubber tube carried as high into the bowel as possible, has seemed to serve a good purpose in cases of deficient excretion of urine; and in pneumonia and uremia to keep up the good effect previously obtained by hypodermoclysis." Here the allusion is to the use of physiologic salt solution in pneumonia as a well-known practice, and the original contribution, if any, is regarding the coincident use of venesection.

In the article in the *Philadelphia Polyclinic* for October 15, 1898, on "Therapeutic Saline Solutions and Their Uses," the following occurs: "I have used both venous infusion and subcutaneous infusion with great satisfaction and much success in uremic conditions, including actual coma. In such cases it is well to precede or accompany the introduction of saline solution by bloodletting. The same remarks will apply to the coma of delirium tremens, as exemplified in a case recently under my care at the hospital, and which Dr. Torrance, our efficient and skilful resident, published in a recent number of the *Philadelphia Polyclinic*. In a severe case of measles in an adult seen last spring in consultation with Dr. M. Staller of this city, and in which acute nephritis with hematuria and a massive catarrhal pneumonia were the complications, wet cupping over the kidneys, followed by hypodermoclysis with therapeutic saline solution (sodium chloride, 0.75 per cent.) seemed to be largely responsible for the patient's recovery. The hypodermoclysis was repeated several times at intervals of twenty-four to forty-eight hours. In a case of pneumonia in an elderly patient with diabetes hypodermoclysis with therapeutic saline solution (sodium chloride, 40 grains, sodium carbonate, 20 grains, to the pint of sterilized water) restored the interrupted flow of urine, and averted the coma that seemed threatened by the semi-stuporous condition of the patient. In this case, after the acute danger had passed, a quart of saline solution was thrown high into the colon, daily. Much of this was retained and it seemed to have a good influence upon the kidneys." All these publications were made prior to the very excellent paper of Dr. Clement A. Penrose on "Infusion of Salt Solution Combined with a Special Method for the Administration of Oxygen Inhalations as a Treatment in Pneumonia," in the *Johns Hopkins Hospital Bulletin*, No. 100, July, 1899, reporting his first case treated February 14, 1898.

The most complete publication, however, upon the subject of this article, was printed in the *International Clinics* (Vol. 4, 9th series, 1900), by Dr. Henry, in which he reports twelve cases treated in 1889 and in 1899, in ten of which recovery took place, two terminating fatally. In this communication reference is made to Dr. Cunningham's paper and to that of Dr. Beverley Robinson, the latter of whom suggests the employment of hypodermoclysis after bleeding, as to which specifically combined procedure, therefore, he preceded the writer in publication, though not in practice. Dr. Henry, himself, advances no claim to priority, although he seems to have been the first to employ the method systematically. It is a good method and should be resorted to with far greater frequency than is the ordinary custom. As we said of the use of oxygen in our editorial of 1892, so may we say of hypodermoclysis, that to get the best results it should be used in time, and that it is foolish to wait until the patient is dead, expecting then to bring him to life either with salt or with oxygen.

It is to be hoped that the discussion as to priority if it have no other effect, will strongly direct professional attention to the great usefulness of the method, and thus indirectly lead to the saving of many a life.

ECHOES AND NEWS.

NEW YORK.

Physicians for the Tenements.—At a recent meeting of the Board of Health of New York City it was decided to have the summer staff of physicians of the Board pay visits to the tenements during the summer and alleviate all cases of sickness among the poor. The visits will commence on July 8th. The Board will refer all appropriate cases to the summer staff for treatment.

Floating Hospital Service.—The floating hospitals of St. John's Guild will start their summer's service for the children of the poor on Monday, July 8th, and thereafter the two hospitals will make trips every day except Sunday, one running on the North River and one on the East River.

Ravages of Heat in New York City.—The heat for the past week has been excessive and as usual under these conditions has caused much suffering and numerous deaths. During the first four days of the present week the deaths directly attributable to excessive heat in Greater New York exceeded 250 and the number of prostrations reported reached 400. It is safe to say that many cases of heat exhaustion were cared for privately and are not included in this number.

New Tenement Law.—The Department of Health has now taken notice of the several clauses of the Tenement-House act, which has become a law. It has sent out the circulars embodying the text of the law, most of which has been in force for considerable time past. This circular, addressed to the owner, lessee, or agent of the house, contains the portions of this law which are new, as follows:

"A tenement house shall be subject to a penalty of $1,000 if it or any part of it shall be used for the purpose of a house of prostitution or assignation of any description, with the permission of the owner thereof or his agent, and said penalty shall be a lien upon the house and the lot upon which the house is situated. A woman who resides in or commits prostitution in a house of prostitution or assignation of any description in a tenement house, or solicits any man or boy to enter for such purpose a tenement house, shall be deemed a vagrant, and upon conviction, shall be committed to a county jail for a term not exceeding six months. If a tenement house is used for purpose of prostitution or assignation or any part thereof, with the permission of the lessee or his agent, the lease shall be terminable at the election of the lessor. A tenement house shall be deemed to have been used with the permission of the owner and lessee if summary proceedings for the removal of the tenants of so much thereof as is unlawfully used shall not have been commenced within five days after notice of such unlawful use served by the Department of Health. Whenever the liens upon a tenement house shall amount to $1,000 or over, the Department of Health shall appoint a receiver of the rents and profits of said property."

Until the new Tenement-House Commissioner is appointed the responsibility so far as the Board of Health is concerned for the Borough of Manhattan will rest principally upon the shoulders of Dr. Frederick H. Dillingham, Assistant Sanitary Inspector.

PHILADELPHIA.

Prostrations from Heat.—The excessive heat of the last days of June has been responsible for many prostrations and several deaths. There were 8 deaths directly attributable to the heat on June 29th and at least 4 on June 30th. Hospitals having yard facilities for heat tents are treating the greater number of cases, but the others are receiving many cases daily.

St. Joseph's Hospital.—Dr. J. Chalmers Da Costa has resigned as surgeon. The vacancy has been filled by the appointment of Dr. Charles F. Nassau.

Philadelphia Hospital.—The appointment of 24 resident physicians for the year beginning July 1st has been made. The Woman's Medical College of this city numbers two of its graduates among this number.

Death of Pennsylvania's Oldest Practitioner.—Dr. J. Augustus Ehler died at his home in Lancaster June 29th at the age of eighty-seven years. He was supposedly the oldest practising physician in the State and had been in active practice for sixty years. He was one of the founders of the Lancaster City and County Medical Society and of the Pennsylvania State Medical Society.

Site for Almshouse.—The special committee of inspection, after making a tour of the islands of the Delaware River, has decided that Petty's Island, opposite the northern section of the city, offers the best advantages as a site for the new buildings. The island, however, belongs to New Jersey and its concession is necessary before operations are begun.

Eosinophilia in Trichinosis.—At the Pathological Society, June 27th, Dr. R. C. Rosenberger read a report of the pathological findings in a case of trichinosis in St. Joseph's Hospital under the care of Dr. J. Chalmers Da Costa. The only part of the body affected was the right leg and thigh. Encapsulated trichinæ were found in the muscles, many of the capsules being surrounded by accumulations of lymphoid cells. Four blood-counts showed eosinophiles, varying from 2.5 to 4 per cent. The conclusion reached was that eosinophilia was not pathognomonic of trichinosis. An extended review of the literature showed that marked eosinophilia was met with at times in numerous other diseases. In discussing the paper Dr. W. M. L. Coplin suggested the prob-

ability of a recrudescence of lesions in the case. This would be borne out by the lymphoid cells found around the older capsules, the absence of eosinophilia which is commonly marked in initial outbreaks of trichinosis, and by the history of injury which sets up activity in encapsulated parasites of other forms.

Medico-Chirurgical Hospital.—Medical circles are much interested in the attack made by the *Times* on the Medico-Chirurgical Hospital during the past week. In commenting on the large appropriation, $190,000, received by the hospital from the State, if the Governor signs the bill, comparison was made between the proportion of free patients treated by that and other hospitals. Statistics quoted show that 54 per cent. of its patients during 1900 were free. Compared with this the Pennsylvania maintained nearly 96 per cent. and the Episcopal 94 per cent. of their patients free. Neither of these hospitals receives State aid.

CHICAGO.

Resignation of Dr. Robison.—Dr. John A. Robison has resigned the Assistant Professorship in Medicine in Rush Medical College.

Officers of the Chicago Society of Internal Medicine.—At the annual meeting, held June 27th, the following officers were elected for the ensuing year: President, Dr. Edward F. Wells; Vice-President, Dr. George W. Webster; Secretary, Dr. Robert B. Preble; Treasurer, Dr. M. L. Goodkind; Censor, Dr. John M. Dodson.

Reform at the Cook County Hospital.—Some of the new rules now being enforced at the Cook County Hospital are as follows: No person suffering from delirium tremens will be admitted to the institution. Heretofore, owing to lack of other accommodations, these victims of drink have been placed in wards occupied by patients suffering from fever and other serious ailments, to the detriment of the latter. Solicitors for attorneys seeking damage suits, claim agents seeking to make settlements with those whose have suffered personal injuries, and "runners" for undertakers who are seeking to increase their business will be denied admission. Political pulls will keep no employees of the hospital who fail to perform their full duty in their places. All discharges of patients will be made only by senior internes, subject to the approval of the Warden. A clinical director, to be selected by the County Civil Service Commission, will be added to the hospital staff at a salary of $1,200 a year. The Executive Committee of the attending medical staff will meet with the Warden each month. For some years these monthly meetings have been dispensed with, and there has been friction between the physicians and the Warden.

To Erect a New College.—Plans for a new college building and hospital, to cost $100,000, were discussed by the Directors of the American Medical Missionary College at their annual business meeting recently. It is thought that the building will be put up near the Cook County Hospital.

Prevention of Illegal Trade in Narcotics.—To prevent the illegal and ever-increasing sale of narcotics in the downtown district, the First District Auxiliary Association of Pharmacists has been formed. The sale of cocaine and morphine in the levee district has greatly increased during the last year, and it is estimated that more than three hundred ounces of the former drug are sold monthly to persons addicted to its use. This is procured without physicians prescriptions, or other authority, the statutes governing its sale being openly violated. Apathy on the part of the City and State officials is said to be the cause of the laxity of the druggists. A committee was appointed to investigate the matter. A more rigid adherence to the provisions of the new State Pharmacy Act, pertaining to registered and competent assistants, also will be required by the Association, and the assistance of the State's Attorney will be asked for its endorsement.

Fire at the College of Physicians and Surgeons.—A bolt of lightning, striking the dome of the building of the College of Physicians and Surgeons, June 25th, set fire to the top floor, where the anatomical and physiological laboratories were situated. The damage done to the college building is estimated at $30,000. The college is insured for $100,000. The physiological laboratory outfit, consisting of apparatus that cost over $15,000, was all destroyed. The damage to contents would have been far more serious, but for the fact that many valuable pieces of apparatus had been taken the day before to the West Division High School, which building has been recently purchased by the College.

GENERAL.

Hospital-Ship "Maine."—The Earl of Selborne, First Lord of the Admiralty, announced in the House of Lords that he had great gratification in informing the House that the hospital-ship "Maine," which was fitted out by a committee of American ladies for the use of the wounded and sick in South Africa and which later was sent to Taku, where she took on board wounded and sick men of various nationalities, had been presented as a gift to the British navy. The hospital-ship "Maine," originally was loaned by the Atlantic Transport Company, through its president, Bernard Baker, of Baltimore, Md., to a committee of American ladies, who fitted the vessel up as a modern hospital ship, placed her in charge of American doctors and nurses, and sent her to Cape Town and Durban to care for the wounded and sick in the South African War. At Cape Town and Durban she received both the British and Boer wounded and sick, and in due course of time returned to Southampton with more than 350 invalided British soldiers.

She was re-equipped there in nine days and sent back to South Africa to bring home another shipload of invalids.

Census of European Nations.—The census returns show the population of France to be, in round numbers, 38,600,000, an increase of 330,000 on 1896. To this small increase Paris and its suburbs contribute 292,000, the greater part of which number is due to foreign immigrants, so that the rest of France gives an increase of only 38,000. Since 1850 the population of France, allowing for alterations of boundaries, has only increased from 35,000,000 to 38,000,000, whereas that of the United Kingdom has risen from 27,000,000 to 41,000,000, Germany from 35,000,000 to 56,000,000, Austria from 30,000,000 to 45,000,000, Italy from 23,000,000 to 32,000,000 and Russia, partly owing to annexations, from 66,000,000 to 128,000,000.

Honorary Degrees for Medical Men.—Several medical gentlemen have been honored with honorary degrees this year. In addition to Professor George M. Lefferts of New York, who received the degree of Master of Science from Columbia, as already mentioned in a previous issue of the MEDICAL NEWS, Professor Theobold Smith of Boston and Professor Otto G. Ramsay of New Haven each received the honorary degree of Master of Arts from Harvard and Yale respectively.

Dr. Koch and the Treatment of Consumption.—A commission, of which Dr. Koch is President, recently visited the Consumptive Hospital at Slawentzitz, in Upper Silesia. The main object was to investigate the use of tuberculin, which for the past decade has been the sole medicinal remedy applied there. Dr. Koch expressed his complete satisfaction at the results of the visit, especially in regard to the treatment. Unfortunately this has not been the experience of others who have given tuberculin a fair trial.

Gift to a Medical Society.—Dr. J. Ewing Mears of Philadelphia has given to the Marion County (Ind.), Medical Society property in Indianapolis valued at $25,000, on which to erect a home for the Society as a memorial to his father, who was a pioneer physician in Indianapolis.

Army Medical Notes.—Major John Carling, Surgeon, United States Volunteers, having tendered his resignation, is honorably discharged from the service of the United States, to take effect July 3d.

Major Damaso T. Lainé, Surgeon, United States Volunteers, is relieved from duty in the Department of Cuba and will proceed to San Francisco for transportation to Manila, Philippine Islands.

Navy Medical Notes.—The following commissions of naval officers were signed by the President last week: Alfred W. Balch, as assistant surgeon with rank of lieutenant, junior grade; William H. Bucher, passed assistant surgeon, rank of lieutenant, junior grade.

Passed Assistant Surgeon R. S. Blakeman is ordered to Norfolk Hospital, July 2d.

Bubonic Plague in Portugal.—Press despatches announce the presence of bubonic plague in Oporto, Portugal. It is said that 12 cases have been reported, with 4 deaths.

Chemistry, Pasteur's Weak Point.—In a life of Pasteur, published in Paris, attention is called to the fact that the man who was destined to revolutionize chemistry came fourteenth in the list of twenty-two candidates at his high school in Dijon, and was marked "weak" in chemistry! His researches in regard to the disease of silkworms are said to have been the means of saving France a sum equal to that paid to Germany as the price of peace. When Napoleon III. became acquainted with Pasteur, what especially excited his wonder was that the eminent man of science had made no attempt to obtain a "legitimate profit" from the commercial application of his labors.

Famine Record in India.—A Blue Book on India, just issued, shows that $90,000,000 was expended for the relief of famine sufferers during the year 1899-1900. The mortality from the plague for the five years ending March, 1901, was nearly 600,000. The census completed in March, 1901, shows that the increase in population during the past ten years was only from 5,000,000 to 6,000,000 instead of the normal 19,000,000. The loss represents deaths from famine and the decrease in births in consequence of the famine.

The Law in its Relations to the Practice of Medicine.—In an article contributed to the July *Forum*, Mr. Champe S. Andrews, counsel to the New York State Medical Society, presents with admirable clearness and force the present status of the law in the several States in regard to restrictions upon the practice of medicine, emphasizes the grave need that there should be everywhere an adequate, accurate, and intelligent definition of what it is to practise medicine, and shows that law and reason are alike against the charlatans who, under various names strive to make the constitutional guarantee of religious freedom a defense against interference with their exploitation of human ignorance and credulity. With complete success Mr. Andrews attacks the grotesque fallacy that the practice of medicine necessarily involves the administration of drugs, and shows that it is not the use of any particular means or method of healing, but has reference (1) to the proper diagnosis of disease, and (2) to the utilization of all means by which disease can be prevented, alleviated or cured.

Harvard's New Medical School.—For several years it has been an open secret that the present facilities at the Harvard Medical School were

entirely inadequate to the growing requirements and that a complete, greatly enlarged and modern plant, consisting of a central administration building, with at least five detached laboratory buildings, including a hospital, was to be erected upon a elegant site that has been secured on Huntington Avenue. It was supposed that the carrying out of the plan would be a matter for the remote future. Nevertheless, the medical Faculty, through a committee consisting of Drs. Henry P. Bowditch and J. Collins Warren, proceeded to draw up plans and specifications for the buildings, which they would like to have and could use next year, if they had them. There would be five large buildings besides the power house. The estimated cost is $2,000,000. Last Friday Dr. Warren received a cable message from Mr. J. Pierpont Morgan, in which he said: "Referring to our conversation and plans submitted, I am prepared to erect the central buildings and two side pavilions as a memorial to Junius Spencer Morgan, a native of Massachusetts and for many years a merchant of Boston. You can announce this." When President Eliot made his announcement of the gift from Mr. Morgan he left the announcement of the donor's name to the very last, as the signature to the cable message to Dr. Warren. Thereupon the crowd went wild, ending in nine Harvards for Mr. Morgan. President Eliot called attention to the phrase "plans submitted," which, he said, included specifications that called for an outlay of more than $1,000,000.

Obituary.—Henry G. Wagoner, M.D., County Physician, of Somerville, N. J., died suddenly July 1st of apoplexy. He was seventy years old and prominent in Masonic and medical societies.

Dr. Charles A. Littler, a prominent physician, of Jackson, Mich., was found dead in the woods twelve miles south of his home July 1st. His jugular vein had been severed, and near the gaping wound was a scalpel, which had been taken from his case of instruments. Dr. Littler was independent financially, and, so far as known, was happy. He was on his way to perform an operation on a patient two miles from where his body was found.

Dr. John K. Curwin, eighty years old, died suddenly of heart disease yesterday at Harrisburg, Penn. Dr. Curwin built the Harrisburg Insane Hospital, and was its first Superintendent. He was subsequently Superintendent of the Warren State Insane Hospital. He served several times as a Commissioner to the Presbyterian General Assembly from the Carlisle Presbytery.

CORRESPONDENCE.

THE VIRCHOW FUND.

To the Editor of the MEDICAL NEWS:

DEAR SIR: Some months ago a Committee, consisting of Dr. Reed, President of the American Medical Association, Dr. Bowditch, President of the Congress of American Physicians and Surgeons, Dr. Weir, President of the New York Academy of Medicine, Dr. Welch of Johns Hopkins University, and the undersigned Secretary, published an appeal to the American medical profession requesting contributions to the Virchow Fund which was established ten years ago in honor of Rudolf Virchow's seventieth birthday, which was reached October 13, 1891. The Fund was created for the purpose of fostering biological, anthropological and general medical research. A large German Committee, with national Committees formed all over the globe, has undertaken to increase this Fund in honor of the coming eightieth birthday of the great medical reformer.

Whatever contributions will be raised should be sent to Germany on the first day of September in order to be received and acknowledged by the Central Committee in due time. As our former notices may have been overlooked by such as are anxious to show their appreciation of the great master and to aid the cause represented by his lifelong labors, we herewith repeat our appeal.

A. JACOBI, *Secretary.*

110 W. 34th Street, New York. July 1, 1901.

SMALLPOX.

To the Editor of the MEDICAL NEWS:

DEAR SIR: Your editorial of June 22d, referring to the discussion on pseudosmallpox before the recent meeting of the American Medical Association, has raised a doubt in the mind of the rural practitioner as to the status of the disease. Will you be kind enough to place before the medical profession the microscopic knowledge of smallpox that has been acquired up to the present time, just as has been done for other infectious diseases?

J. H. BILES, M.D.

Teller, Colorado, June 27, 1901.

OUR editorial on "The Smallpox Situation Once More" (MEDICAL NEWS, June 22d, p. 991) in commenting on the discussion on smallpox at the St. Paul meeting of the American Medical Association called attention to the possible existence of a third disease in the smallpox group intermediate to variola and varicella, as German measles is to measles and scarlet fever in the other group of exanthemata. We said that further observations along this line are eminently desirable as the question involved is one of the most important in medicine. We expressly warned, however, against permitting indefinite conclusions and inadequately completed observations to hamper the work of sanitation and universal vaccination which constitute our only safeguard against the smallpox that undoubtedly exists in only too many parts of the country.

With regard to doubts that may be raised in the mind of the practitioner, our editorial was meant to encourage wholesome skepticism, the

blest predecessor of more definite knowledge. To doubt is better than to be too sure. Uncertainty encourages accuracy of observation and this is just what is needed in the present situation in order to settle the vexed question of so-called pseudosmallpox (a term unjustified in the present state of the discussion) and make clear the status of certain doubtful cases that are certainly of the smallpox type.

The finding with the microscope in the present state of our knowledge cannot be of help in the solution of the problem. We are not as yet certain of the microbe that causes the disease. On page 388 of the MEDICAL NEWS, Vol. 78, there is an editorial review of the recent contributions to medical literature regarding the cause of smallpox. Like cancer it seems to be due to a protozoon, but that is all that can be said. However, without knowing definitely its cause, it may be possible to differentiate a disease resembling smallpox from true smallpox, for, after all, it must be remembered that we do not know the cause of either measles or scarlet fever, although we have succeeded in differentiating German measles from them.—[EDITOR.]

OUR LONDON LETTER.

(From Our Special Correspondent.)

LONDON, June 22, 1901.

THE GENERAL MEDICAL COUNCIL—AN ANTIMALARIA EXPEDITION TO SIERRA LEONE—THE FOUR-HUNDRED-AND-FIFTIETH ANNIVERSARY OF THE UNIVERSITY OF GLASGOW—SOME OF ITS MEDICAL GLORIES—THE MEDICAL PROFESSION AND THE WAR OFFICE—PROPOSED DINNER TO THE LATE DIRECTOR-GENERAL OF THE ARMY MEDICAL SERVICE—ANTIVIVISECTIONISM—LORD COLERIDGE AND THE ATHENÆUM CLUB: A RECORD "PILLING"—THE KING AS A PHYSICIAN.

THE General Medical Council, as to the functions of which I had something to say in my last letter, got through its work in a week, a record achievement for that slow moving body. The explanation is that it had not much to do. The principal matter before it was the contumacious conduct of the London Colleges of Physicians and Surgeons in regard to the five years' curriculum of medical study. This extended period of study was made compulsory by the Council a few years ago, and it naturally does not care to see its authority defied by the chief licensing bodies in England. The Colleges accept time spent by boys in grammar schools working at physics, chemistry and biology as constituting one year of the prescribed five of medical study, and virtually reduce the curriculum to four years, thus stultifying the enactment of the Council. The Irish Colleges, as was to be expected, have expressed their intention of following the example of their English sisters. There was an animated debate in the course of which the representative of the Royal College of Physicians, Dr. Norman Moore, declared that he would rather see the registration of medical students done away with than give up the rights, or, as he preferred to call them, the responsibilities of the institution of which he is the champion. The practical outcome of the discussion was that the Council agreed to reconsider a question which it had already decided and thus, in fact, surrendered its position. The whole controversy is largely a question of words, for ever since the establishment of the five-year curriculum one of them has in fact been devoted to subjects which are merely preliminary to the study of strictly medical subjects.

The other work of the Council included the hearing of charges of unprofessional conduct against medical practitioners. A surgeon in the navy was struck off the *Medical Register* for adultery with a patient proved in a public court of law. This sentence involves dismissal from the Navy and professional ruin. Dr. Ward Irvine, the *protégé* of the all-powerful Chamberlain clan, of whom something was said last week, appeared before the Council and was in effect dismissed with a caution. He had been summoned on an earlier day, but did not find it convenient to attend. The Council should really be grateful to him for helping it out of an embarrassing position, for if he had dared its wrath by staying away, it could scarcely, in view of the fact that he had ceased to commit the offence charged against him, have pronounced the sentence of major excommunication upon him. It would, indeed, have been in much the same predicament as a former Speaker of the House of Commons who threatened to "name" a refractory member. On the member inquiring what the consequences of this awful threat would be, the Speaker said solemnly, "God only knows." The situation was saved by the attendance of Dr. Irvine, and the incident is now closed as far as he is concerned, but some of the papers contend, not unjustly, that Mr. Joseph Chamberlain should apologize to the Council. This, it may safely be predicted, he will not do.

It may be mentioned that the Council has been looking into its affairs and has discovered that its financial position is unsatisfactory. It has found it necessary to ask the advice of an expert who, among other suggested retrenchments, proposes that the sessions should be shorter, the fees for attendance smaller and the allowances for travelling expenses less liberal. It is certain that the payment of twenty-six dollars a day to each member is a direct encouragement to exuberance of oratory and a cause of the deliberations of the Council being in Milton's phrase "in linkéd sweetness long drawn out." The medical profession would put up with less "sweetness" if it got more solid benefit from the Council.

Major Ronald Ross recently sailed from Liverpool for West Africa on a crusade against the deadly gnats whose bits breeds malaria. He proposes to attempt the extermination of the whole tribe, first at Sierra Leone, then, if success crowns his efforts, in other settlements along the

coast. He has a number of big Liverpool merchants at his back so there will be no difficulty about the sinews of war. All the supplies for the expedition have been given by merchants interested in its results, one contributing an abundance of oil, another all the cement required, a third a large quantity of chlorine compounds and sulphur, others materials for fumigation, etc. Dr. Matthew Logan Taylor who has been assistant to the Professor of Pathology in the University of Glasgow goes as the Major's assistant, and other scientific helpers will probably join the expedition later. Although the plan of suppressing malaria by the extermination of mosquitoes was advocated by Ross himself in a report to the Government of India in February, 1898, and although it has been carried into execution in Italy and also, I believe, in America, no municipality in the British Colonial possessions—except Hongkong—has hitherto had the enterprise to act on the suggestion. Ross calls this stupidity, but the municipalities would doubtless retort that it is partly at least want of money. Ross himself estimates the cost of the work at Freetown, Sierra Leone, alone as $3,000 a year, and it will probably be a great deal more. If, therefore, he is to rid West Africa of mosquitoes, he will have to carry on a war almost as costly as that in South Africa and of far longer duration, for mosquitoes are "slimmer" even than Boers.

The University of Glasgow has this week been celebrating with appropriate pride, pomp and circumstances, the four-hundred-and-fiftieth anniversary of its foundation. Like the other universities of Calvinistic Scotland, with the single exception of Edinburgh, it was founded by a Pope—Nicholas the Fifth, who gave it a constitution on the model of the University of Bologna. Glasgow has the names of many great men on its roll of fame. Among them (to take the classification and examples of a leading newspaper) are "philosophers, theologians, historians, scholars, statesmen, orators and men of science," such as "Bishop Elphinstone, John Knox, Andrew Melville, Robert Baillie, Archbishop Leighton, Bishop Burnet, Thomas Reid, Colin McLaurin, Adam Smith, James Watt, Thomas Campbell, Archbishop Tait, Professor Lushington, and Principal Caird." I have quoted this list as a curious instance of the indifference to the work of medical explorers and discoverers that prevails even among those whose business it is to lighten the darkness of what the man in the street is pleased to call his mind. I am not concerned to dispute the greatness of the men mentioned above, though I think it doubtful whether the celebrity of some of them has traveled across the Atlantic. But if the whole batch were placed in the scale of real achievement against the single name of Lister, is it not the simple truth that they would kick the beam? Lister was connected with Glasgow in his early days, and it was there that he made his first gropings toward the far-reaching truth of which he has been at once the prophet and the apostle. Another of Glasgow's glories is Professor Macewen who is held by many here to be the very best surgeon in the United States. But he is one of Carlyle's strong silent men, and the outside world hears little of him. A characteristic incident will show what manner of man he is. Some thirteen or fourteen years ago Victor Horsley published a successful case of removal of a small tumor of the theca and was straightway hailed, not only by the profession, but by the public as the pioneer of brain surgery. In 1888, when the British Medical Association held its annual meeting at Glasgow, a hard-featured, *dour*-looking man delivered an address in which, without ostentation, he gave particulars of various operations performed by him on the brain during the previous nine or ten years. The effect was electric; the whole meeting sprang to its feet and cheered till it was hoarse. It applauded not merely the achievement, but the character of the man who had slowly built up his cairn of truth without proclaiming the fact from the housetops every time he laid one stone on another, as is the fashion with too many enterprising operators. Macewen is in the sphere of surgery a man of action; he has done much but written little, but what he has written is nearly all pure gold. Another Glasgow celebrity who might be claimed for medicine is Sir Joseph Hooker, the famous botanist who for many years was the presiding genius at the Royal Gardens, Kew. He took the degree of Doctor of Medicine at Glasgow in 1839, and, like his friend Huxley, served for some years as a surgeon in the Navy. Hooker was also an intimate friend of Charles Darwin. Of Sir William Gairdner, late Professor of Medicine at Glasgow, something was said in last week's letter. Though he now lives at Edinburgh, his name must always remain associated with Glasgow where he did much to form the minds of successive rising generations of medical men.

The temper of the profession is gradually rising as it recognizes more and more clearly that the slights put by the Secretary of State for War on the Medical Service of the Army are part of a fixed policy. How the Director-General, Dr. Jameson, was driven from office has already been related. Since then various incidents too petty to chronicle, but none the less irritating to those concerned, have occurred, and it is plain that Mr. Brodrick is for some inscrutable reason of his own at war with the doctors. The result is that there are no candidates for commissions in the Service. There is in London a physician whose special line of business is the "cramming" of men for the Army examinations. Practically all of them go through his hands, and the authorities of the Medical Department have thus been able to form an accurate forecast of the numbers likely to present themselves for the various services. At present there is said not to be a single man preparing for either the Army or the Navy; and there are only five for the Indian Medical Service which a few years ago attracted many ambitious men. Such are the consequences of the

profound distrust which has been bred in men's minds by the attitude which the Government has thought proper to assume towards the medical officers in the service of the Crown. The War Office in particular needs to be continually reminded of the fact that, while the Army cannot do without doctors, the medical profession can perfectly well do without the Army.

As one way of expressing its feelings on the subject, the profession is to give a complimentary dinner to the late Director-General of the Army Medical Service. It is intended to make it fully representative of the profession in Great Britain, and as the movement has already received the approval of the Presidents of all the Colleges and of the heads of the profession in the three kingdoms, its success may be regarded as assured. Though not professedly a manifestation against the Secretary of State for War, the dinner is in reality designed for that purpose. It will in fact be a declaration of war between the profession and Mr. Brodrick. The issue can scarcely be regarded as doubtful for the profession has the Secretary of State virtually at its mercy.

It was mentioned in a previous letter that the antivivisectionists are once more on the warpath. They are trying to induce charitable persons to withhold subscriptions from hospitals on the avowed ground that some of the physicians and surgeons on the staffs of those institutions are or have been vivisectors. Even this, as a bald statement of fact, is likely to mislead the public. But the philozoic fanatics go much further than this by insinuation, for they speak of "living human beings" in hospitals, being handed over to the tender mercies of "physiologists," obviously with intent to produce the impression that patients are used for experiment. They have "sandwich-men" parading the streets with gruesome pictures of mutilated dogs, etc., in the lurid style of the low prints which try to make the public's flesh creep by illustrations of the latest murder. I fancy our antivivisectionist friend are overdoing it. At the Athenæum Club the other day, Lord Coleridge, ex-President of the National Antivivisection Society, was black-balled in a most signal manner; he got 68 "pills" in a total vote of about 240—probably a record. The Athenæum is our leading club in respect of the literary, scientific and personal eminence of its members, and therefore it is regarded as a social distinction to belong to it. Lord Coleridge's rejection was brought about by the "doctors" in spite of the strenuous support of bishops, deans and judges with which the Club swarms.

The King has "honored" the Royal Medical and Chirurgical Society by signing its roll. His Majesty is already a Fellow of both the London Colleges, so that he may be claimed as a "doubly qualified" member of the medical profession. By the way, people are noticing more and more his strong resemblance in face to Henry VIII. A further coincidence is that "Bluff King Hal" was, according to Froude, one of the best physicians of his day; he was likewise the founder of the Royal College of Physicians of London of which his descendant (for our Royal family lays great store on its supposed possession of an infinitesimal portion of the blood of the older Kings of England) is now an ornament.

TRANSACTIONS OF FOREIGN SOCIETIES.

German.

SPINA BIFIDA OCCULTA—SPINAL PARALYSIS IN CHILDREN—BABINSKI'S SIGN OF NERVOUS DISEASE—EARLY TABES DORSALIS AND SYPHILITIC GUMMA—CARCINOMA OF THE NASOPHARYNX—DIABETES AND TRAUMA—PERNICIOUS ANEMIA AND THE LOSS OF BODY ALBUMINS.

KATZENSTEIN, at the Berliner medicinische Gesellschaft, May 8, 1901, read a paper on the pathology of spina bifida occulta and presented several patients in whom he had been able to obviate or decrease the nervous symptoms by a resection of the membrana reuniens posterior, which had been the source of pressure upon the cord.

PLACZEK in a contribution on spinal paralysis in children gave the clinical and anatomical findings of a case of this class which after three months' suffering died. In the spinal cord the anterior gray horns were diseased practically throughout their length. In addition to this there were degenerations and even atrophy in the muscles and peripheral nerves. In the gray matter the ganglion cells were greatly degenerated and often entirely absent. In addition there was present a great vascular proliferation with a small-cell infiltration of the lymph-spaces about the adventitia. The glia had been split up but nowhere was it really proliferated. The white substance was everywhere normal. Upon these facts the contributor argued that between the two opposite sources of the disease, namely the ganglion cells and the vessels, he was inclined to think that the latter obtained.

L. MICHAELIS, at the Verein für innere Medicin in Berlin, May 6, 1901, showed the preparation of a brain-tumor taken from a young girl. During life the girl had shown Babinski's phenomenon in the right foot, hence the inference was made that the growth was in the left motor tract. It was found in the left medullary substances. From his observations in hospital practice he was led to the belief that whenever the Babinski sign is present there is an organic nerve-lesion behind it.

PLIHN showed the spinal cord and brain from a case of early tabes dorsalis. There was a cheesy connective-tissue mass grown upon the cord and upon the cortex of the brain. Examination showed that there were no tubercle bacilli in it. From this it was concluded that the nodes must be syphilitic, which makes the case a rare contribution to the cause of the disease, usually assumed as syphilis.

A. FRAENKEL presented a specimen of primary

carcinoma of the nasopharyngeal space which had extended by direct contiguity to the base of the skull and spinal column and finally led to the breaking off of the odontoid process. Death did not suddenly follow this accident. The chief symptoms were paresis of the various cranial and cervical nerves and very great pain. The effort of the patient had been to keep his head absolutely still, using his hands as support. The clinical diagnosis had been some form of bone disease, apparently caries.

LITTEN took up the relation between diabetes and traumatism and related the facts of a case in which he had been interested. In December, 1894, a gentleman fell on the sidewalk sustaining a severe injury to one hip which soon began to swell enormously. The next day pain of excruciating degree appeared and was followed by coma. He was then removed to the hospital where three per cent. of sugar was found in his urine. After ten days of uninterrupted coma the man died. The two questions for settlement are, was the accident the cause of death, namely, by first having produced the glycosuria, or did the sugar indicate a diabetes which was at the bottom of the whole history, making the coma entirely due to that? He felt that the answer to the former question must be negative on the grounds of the various details in the history and that the second question must be affirmatively answered.

STRAUSS said that in his experience he had seen several examples of alimentary temporary glycosuria produced by accident. He is of the opinion that trauma may induce a relative failure of assimilation of the carbohydrates. Jastrowitz stated that he had a patient in whom fear alone had caused a diabetes.

E. ROSENQUIST (Helsinfors A. G.) stated that for many years he had been studying pernicious anemia, especially botriocephalus anemia; and had long ago claimed that such anemia is accompanied by a great loss of the body albumin. Other authors had at once disputed this and held that when the albumin loss is very great there is always some other pathological process at the bottom of it. Various experiments by Strümpel, Eichhorst and others appeared to be the foundation of their theory, but to-day these observations would not be accepted as conclusive proof. In his native town he has had an unusually fertile field for observing bothriscephalus anemia, and the following are his results: In fifteen patients afflicted by the parasite, he found in eleven a great loss in albumins, ranging from 0.5 to 6.6 grams per diem, before the driving-out of the worm; after the elimination of the worm he saw from day to day a resumption of albumins. This restoration was not an absolute one, but with some variations was on the whole and in a general way a balance of the loss. This increase in the nitrogenous substances of the body also occurred when there was unfavorable dietetic surroundings. It seemed, therefore, that as soon as the worm is driven out the tissue-building forces of the body again become active. The loss in albumin is present not only on the part of the blood, but also in all the tissues. The explanation of this loss lies very likely in a poison given out by the worm itself. The anemia alone can not be its source. The question as to why in the regular presence of this toxic substance among so many patients suffering from the worms so very few show a pernicious anemia, may be fully answered by assuming an individual vulnerability. The number of red cells followed in regular proportion the degree of albumin loss, but in seven of his patients he noticed that there was hardly a change in the condition of the red cells. Whether this was due to a peculiar resistance of these red cells or to an increased activity in the production of the cells or to both combined could not be decided. He has also observed a similar state of affairs in three patients with kryptogenetic anemia, which also appears to be toxic in its origin. No distinctions between the two kinds are discoverable.

SOCIETY PROCEEDINGS.

AMERICAN MEDICAL ASSOCIATION.

Fifty-Second Annual Meeting, Held at St. Paul, Minn., June 4-7, 1901.

SECTION ON DISEASES OF CHILDREN.

FIRST DAY—JUNE 4TH.

Chairman's Address.—This was read by Dr. Samuel W. Kelley of Cleveland, Ohio, who said in part: The advancement of the surgical side of pediatrics is very important, and has been slower in its developments than the medical. In the cases of children abnormalities are found and the same diseases that occur in adults are marked by different phenomena. All are aware what peculiarities surround operative work upon children; how ill they bear hemorrhage, cold, or prolonged shock, and how wonderfully they recuperate once the stress of the storm is passed. The surgeon should at least be required to extend his knowledge to diseases of children.

Measles.—Dr. J. B. Garber of Dunkirk, Ind., said in his paper that the poison of measles spreads by contagion from one person to another and is given off by the breath and secretions. The period of incubation is now well established, and is found to be about fourteen days from the time of exposure. The prodromal symptoms last about three days, and are associated later with catarrhal symptoms. Fever is always present, coming on as early as the second day; often remitting and rising again just preceding the eruption; laryngeal cough, drowsiness, loss of appetite and vomiting usually occur; sometimes convulsions. On the third or fourth day the eruption appears, usually preceded by Koplik spots which

disappear as the eruption progresses. When the rash begins to disappear, if the fever continues, complications are to be feared; for in complications lie the danger of measles.

Dr. Slagle stated that he rarely found Koplik spots. Second attacks of the measles have not been common in his experience. Usually when a second attack is diagnosed as measles, it has been found that it was German measles.

Dr. J. M. Postle was sure that he had seen true measles recur in several cases, and had found benefit in the treatment of measles from the internal administration of suprarenal glands.

Dr. Barber called attention to the danger of endocarditis following measles. Dr. Townsend regarded enlargement of the post-auricular glands as pathognomonic of German measles.

Pathology and Treatment of Pertussis.—Dr. J. M. Postle of Hinckley, Ill., presented the next paper in which he said that pertussis is a toxic neurosis produced by a bacterium probably by that of Czaplewski, Hensel and Koplik, invading the tissues beneath the mucous membrane of the respiratory tract. These bacteria produce a toxin which has as the point of special selection for attack the nerve-cells governing expiration. These nerve-cells are depressed with resulting clonic spasm of the expiratory muscles. Excess of carbonic-acid gas in blood produces powerful stimulation of the nerve-cells governing inspiration, at the same time, partially or completely destroying the toxin. Children, therefore, when playing around gas works have whooping-cough lightly. The treatment consists of the administration of suprarenal glands, strychnine, or any preparation of nux vomica which may be given hypodermatically or by the stomach, and should be pushed almost to the full limit or slightly toxic effect.

Antenatal Treatment of Hemophilia.—This paper by Dr. J. W. Ballantyne of Edinburgh, Scotland, was read by Dr. Darnell. Hemophilia is clearly and persistently hereditary. The probability is that male offspring will be hemophilic, though the female offspring usually escapes. There is a presumptive diagnosis of antenatal hemophilia when such a woman is pregnant with a male infant. The following case is reported; Mrs. C., thirty-four years of age; third pregnancy; tall, well built; rather spare with black hair, sallow complexion; has always lost much blood at her menstrual periods and had postpartum hemorrhage after both previous confinements. She has a distinct family history of hemophilia and the first child at birth was white and anemic but is a marked "bleeder" having nearly succumbed several times during the cutting of teeth. The second infant, a male, showed hemorrhage from the umbilical cord at birth and died at the age of twelve months during dentition, the cause of death being returned as cerebral hemorrhage. When the mother became pregnant for the third time, I advised that chloride of calcium be given to the mother trusting that it would pass through the placenta and reach the fetal tissues, although theoretically, the hope of success was small; iron, arsenic and strychnine were also administered in order to improve the general health, increase the tone of the uterine muscle, and lessen the risk of postpartum hemorrhage. This treatment was carried out for three months. On October 3, 1900, a male child was born, red, mottled, and healthy in appearance—indeed, in all respects normal; there was no hemorrhage from the cord, no postpartum hemorrhage for the first time in the mother's obstetrical history, and she was able to nurse her infant. The child has never had any bleeding, and did not bruise like his brothers. There are circumstances which encourage the opinion that, after all, the treatment in this case may have something more than a coincidental relation to the healthy state of the third infant.

SECOND DAY—JUNE 5TH.

Symptoms of Typhoid Fever in Infancy and Childhood.—Dr. J. P. Crozer Griffith of Philadelphia read this paper. The symptoms of typhoid fever in children differ in many respects materially from those seen in adults. To insist that the cardinal symptoms must always be present would lead us into frequent errors in diagnosis. The affection is far from rare in infancy and the failure to recognize it is rapidly disappearing, because we are more on the alert for it, and have the serum reaction test to aid in the diagnosis. The peculiarity of the onset of typhoid in children is its indefiniteness. The great degree of malaise and fatigue is absent. There is loss of appetite, slight indisposition and some headache. The temperature does not abate and, although the child scarcely feels ill, the diagnosis of typhoid fever may be made by exclusion. The child is sent to bed on general principles and not because it wants to go. In the second class of cases the onset is sudden, with vomiting and fever from the start and the rash is discovered. Perhaps only the Widal reaction will differentiate the disease from indigestion, enteritis or influenza. Another peculiarity is that the course of the disease is shortened; abortive cases are common, it is milder than in adult life and the mortality lower. Enlargement of the spleen is usually present but not usually discovered. The pulse is often unusually slow as compared with the rate which one would expect for the same elevation of temperature in other diseases. The temperature curve is similar to that in adults. Not infrequently it rises rapidly without the step-like ascent. Often it remains high without the tendency to morning fall. Towards the end of the attack it falls often with much greater rapidity

than in adults. Indeed the fall may be almost critical at times. The tongue is not as liable to become dry and parched. Diarrhea is more liable to be absent than present. Abdominal distention is not often a troublesome symptom, though often present. Hemorrhage is of rare occurrence. When it does occur it is usually in later childhood. Perforation is also of uncommon occurrence, the infrequence of these two symptoms probably being due to the less pronounced development of intestinal lesions. One of the characteristics is the tendency of the nervous symptoms to predominate over the intestinal. Slight delirium is common, especially at night. A certain degree of apathy is very frequently present especially in very young children. As a rule, the diagnosis can be easily made, but sometimes typhoid fever begins in children with all the appearances of acute leptomeningitis and leads for a time to an entirely erroneous diagnosis.

Diagnosis of Typhoid Fever in the Laboratory.—Dr. John Lovett Morse of Boston protested against the separation of laboratory and clinical methods in the diagnosis of typhoid fever. They should not be thought of separately but together. Both are fallible and both should be used understandingly. The value of the various laboratory tests are unequal. All have their limitations. The Widal reaction is present in 95 per cent. of all cases of typhoid fever. It seldom appears before the second week, but negative tests are very strong evidence against typhoid fever. The reaction may persist in the blood as long as twenty-nine years after recovery from typhoid; hence a positive reaction in the absence of other symptoms is not diagnostic of typhoid, unless one can be sure the patient has never had typhoid. A negative reaction followed by a positive reaction in a dilution of one to fifty is absolute proof of typhoid. The Widal reaction appears in children under the same conditions as in adults, but appears earlier, is feebler and persists for a shorter time than in adults. In infancy the reaction is of less value than in older children and adults, because it may be transmitted to the infant through the mother. When transmitted through the milk it does not persist for more than a week. Examinations of the stools have shown the presence of the typhoid bacilli in from three to five days after the patient has taken to his bed. The test is nearly equal in value to the Widal reaction. The examination of the feces requires a complete laboratory and much expert knowledge and is therefore not practicable for the average general practitioner. Typhoid bacilli may be found in the urine in from twenty to thirty per cent. of the cases, but not until the later stages of the disease. The rose spots almost invariably showed the presence of the bacilli five or six days before the appearance of the Widal reaction. The diazo-reaction is simple and can be made by any one, but as it is also present in tuberculosis, septicemia and other febrile diseases, the very conditions with which typhoid is easily confounded, it is of comparatively little value. The leucocyte count is important and is subnormal throughout the entire course of the disease. An increase in the number above normal means some complication, such as hemorrhage or inflammation or some outside influence, such as cold bathing. If a differential diagnosis is desired between malaria, examination of the blood for the plasmodium malariæ will clear up the doubt. If meningitis is suspected, lumbar puncture should be resorted to. The author concludes that the Widal reaction and the leucocyte count are the most important of the laboratory methods in diagnosis of this disease, because they are practicable and easily carried out, other tests, although perhaps more accurate, are at the same time impracticable.

Treatment of Typhoid Fever in Children.—Dr. Henry E. Tuley of Louisville, O., considers trained nursing of great importance. It is next to impossible for a mother beset with the cares and responsibilities of a household, especially if there are other children, to care properly for a patient with typhoid fever. The dietetic treatment is important. Fresh milk is unsuitable for a regular diet; broths may be given, whey, predigested milk, some of the cereals and the concentrated foods. No regular routine of medicinal treatment is possible. The treatment should be largely symptomatic, only such medicines being given as are absolutely essential. No antipyretics should be given internally. The condition of the heart should be zealously watched, and strophanthus and strychnine administered if it begins to flag, while alcoholic stimulation should be reserved for administration late in the disease. In hydriatic treatment excellent results have been obtained. Full baths, however, are rarely possible in private practice, but frequent and prolonged sponging gives almost equally good results.

Dietetic Treatment of Typhoid Fever.—Dr. Louis Fischer of New York said that the toxemia of the disease shows itself principally on the heart and circulatory system, which should be carefully watched and stimulated as demanded. He then gave a résumé of foods he had used with success in a series of typhoid cases. Foods should be peptonized and, if necessary, sterilized or pasteurized. Salines have proven of great value, especially the infusion of saline infusions *per os* or *per rectum*, and if coma prevails they should be used by hypodermoclysis. Albumin and salt also may be administered subcutaneously. Plenty of water should be given to drink, and this is some cases may be improved by having it charged with carbonic acid gas. If severe vomiting and gastric disturbance exist the food should be given by the rectum. On the other hand, if severe diarrhea and tenesmus be present, feeding

should not be given by rectum, but through the stomach.

Multiple Gangrene Associated with Cholangitis Complicating Typhoid Fever.—I. A. Abt, M.D., of Chicago, reported the case of a female child, aged twenty-one months that came under observation on the fourth day of its illness. The father was in the hospital with a well-marked typhoid. Examination on admission shows the tongue coated, the abdomen tympanitic, the spleen palpable and enlarged. The Widal reaction was positive. Temperature was 103° F., and there was a slight edema of the extremities. About ten days after admission it was noted that furuncles appeared on the scalp and over the scapula of the left side. After the child had been ill about two weeks, an eruption appeared on the back, neck and extremities. At first, papules appeared; later these became pustules, and in a very short time appeared as areas of gangrene. Summing up the affection of the skin, the following features present: In the course of a febrile disease there developed over the body a number of lesions in the following order: Red macules, papules, flaccid vesicles, and blebs. Also pustulated or crusted papules, umbilicated vesicles, and ulcers with a dirty, grayish, moist slough. The ulcers have steep margins, are mostly oval in shape, and vary from the size of a split pea to a penny. The whole eruption impresses one as a multiple embolic process in the vascular system of the upper corium leading to gangrene of the type called infectious multiple gangrene. Autopsy showed the gangrenous areas in the skin which have already been described. The pericardial sac contained fluid. The myocardium was pale and flabby; the lungs were edematous; the spleen was enlarged and showed presence of infarcts; the kidneys were negative; the liver was large, light brownish in color, and distinctly soft. Over the entire surface there were a large number of whitish areas, about the size of the head of a pin. These were surrounded by a red border, and were irregularly scattered throughout the organ. Microscopically, these areas are seen to be due to a necrosis of the parenchyma adjacent to the interlobular vessels. A study of these sections from the liver shows an inflammation of the bile passages, an angiocholitis. The liver also shows the presence of an adenoma.

Treatment of Temperature by Drugs.—Dr. Edwin Rosenthal of Philadelphia in this paper said that a thorough knowledge of the febrile movement, its cause and its dangers, is as necessary as of the drugs to be used. In the choice of remedies, one must use a surprising amount of judgment. The bad influence of too much drug treatment cannot be questioned, but it is a misleading delusion to say that we can always avoid it. Careful investigation proves that no special specific virtues can be designated; for this reason I cannot find one drug which has stood the test of time and impartial judgment. While all the ordinary coal-tar derivatives have been thoroughly tried, none of them are allowable.

Discussion.—Dr. Victor C. Vaughan of Ann Arbor, Mich., drew attention to the fact of typhoid fever occurring less frequently in children than in adults, and explained this fact by the child not getting around and drinking water from so many sources as an adult; this is the reason why typhoid infection occurs less frequently in women than in men. It has also been said that typhoid fever occurs less frequently in cases of pregnant women; cases of typhoid fever seem to be less severe when the infection is a mixed infection, for when there is a mixed infection with the colon bacillus an irritative diarrhea is set up which causes the intestinal canal to be regularly drained of its poisonous contents. It is high time to stop experimenting with antipyretic drugs. If these dangerous drugs are to be used, let us make our experiments on animals and not on human beings. The only way to reduce temperature is by the cold bath. The occurrence of multiple gangrene is an exceedingly interesting matter, and has been found in malaria, smallpox, etc., as well as in typhoid. The fact of being able to diagnose these things by a positive discovery of the bacillus gives us now a clearer insight into the disease.

Dr. Charles Douglass of Detroit found the medicinal treatment of typhoid fever very unsatisfactory; temperature may be controlled entirely by baths and proper regard to the diet. The diet should always be kept down to the point where there is perfect digestion, then fewer baths and less medicine are necessary; he does not agree with the popular idea with regard to the use of calomel in small doses; his experience is that cases which are allowed to preserve quiet bowels continue to a steady recovery; the temperature goes steadily down without purgation if proper care is used in the diet. Feeding should be such as to make the stools normal in character and free from any bad odor.

Dr. F. Wood thought we frequently fed our typhoid patients too much; less food, less medicine and more water give better results than overfeeding. It is very important to provide perfect quiet for these cases. Do not allow them to become restless, talk too much, or be bothered. Do not urge them to eat at all unless they want to eat. Oftentimes injudicious use of milk will cause tympanitis. If hemorrhage occurs, perfect quiet should be maintained by the use of morphine. Quiet is more important in this complication than any medicine.

Dr. Head pointed out the great value of the leucocyte count as an aid to the differential diagnosis between meningitis and some of those forms that come on like appendicitis.

Prolonged Intubation.—Dr. Edwin Rosen-

thal of Philadelphia read a paper upon this subject. With the advent of diphtheria antitoxin the operation of intubation obtained a fixed position. To the antitoxin is also due the very many accurate results obtained in the study of the progress as well as the sequel of diphtheria, especially of the laryngeal type and those most serious cases requiring intubation. By this procedure we are not only able to relieve the impending suffocation, but we cure. Where before we were expectant, now we are more certain. The tubes should be removed within five days unless it be removed by expectoration before and then be no longer required. If the patient requires the tube longer than this time, it will be impossible to state when it may be safely discontinued. Cases in which the tube must be replaced, even after a week, should be considered abnormal and should be classed under the head of prolonged intubations. Welch reports a case in which the patient required the tube eleven months, finally dying of suffocation. Engelmann and others report the same results.

A case is reported in which the tube was worn, being removed occasionally, for a period of thirty-six days.

Gonorrhea in Boys.—Dr. A. L. Wolbarst of New York called attention in this paper to the frequency of this disease in young boys, twenty-two cases ranging from eighteen months to twelve years of age having fallen under his personal notice. The author speaks in this connection of the great value and importance of circumcision. Every case of gonorrheal urethritis he says offers a most eloquent plea for the circumcision of all male infants. Complications occur in young boys similar to those of adult cases, after the disease has lasted several days. Posterior urethritis, prostatitis and epididymitis have occurred in these cases. There was a total inability to pass urine in one case. The disease also lasts from four to six weeks as in the adult, though the prognosis as to complete and early recovery seems usually to be better in children. Prophylaxis consists in the education of the people to the dangers of the disease. Stringent laws should also be passed for the protection of children.

Discussion of Gonorrhea in Boys.—Dr. Edwin Rosenthal of Philadelphia said gonorrhea is seen so frequently that it might be looked upon as an epidemic. Where the gonococcus is present, we can positively determine the existence of the disease and often trace the guilt of the crime where it occurs in the young child. The overcrowding in tenement districts is responsible for perhaps the most of it in the poor. Dr. Clifton Scott did not think that it was confined to tenement houses. There is a great need for education even among men and women of the better classes. When people come to understand that there are not only vicious men but also vicious women, these questions will be looked at in a different light from the present. For the dissemination of gonorrhea among young boys, servant girls and maids who force connection upon them and thus give first lesson in vice are largely responsible. Formerly it was not thought unsafe when sleeping accommodations were limited by reason of visitors or for other causes, to allow the young boy of ten or twelve years of age to sleep with the maid. Often with result that the innocent boy had been infected with this vicious disease. Dr. C. F. Wahrer referred to the fact that it was not such an unusual matter for children under the age of puberty to indulge in sexual gratifications. A case came under his view in which a boy of thirteen was invited by one of his companions to meet a certain girl of sixteen years of age at a barn where he was shown how by his companion and was then given his first lesson. When the matter was traced up, the girl confessed with unblushing effrontery that she had been engaged at this sort of thing for a long time and spoke of the special enjoyment it was to instruct the new subject.

Dr. A. C. Cotton referred to the astonishing ignorance of the laity, even well informed people, upon this subject. The number of alleged assaults upon little girls is remarkable in number and it is astonishing how many causes of gonorrhea occur in small children. One source of this in the cases of the little girls is where some brutal man while he does not lacerate or cause an injury to the little child, seems to get a peculiar gratification in rubbing his organ against the little one's thighs. The girls of course develop gonorrhea. Intercourse among children before the age of puberty oftentimes occurs. In his dispensary service there was a string of eighteen or twenty little girls whom we found on investigation had come from the same neighborhood. They were of a variety of nationalities. On tracing the matter up it was found that a ten-year-old boy with one of these mature and vicious faces and of course with complete ignorance of what he was doing, had been infecting these eighteen or twenty little girls. Mothers and fathers, especially the latter, with an old gleet not uncommonly infect the innocent child by allowing them to use the same chamber that they have previously used themselves.

Dr. Cook thinks that the time has arrived when the public should be educated on these matters and when they should all know the life history of the gonococcus outside of the human body. Prophylaxis and a thorough knowledge of the dangers of the disease should be taught thoroughly to every patient who comes for treatment. Many cases spread the disease innocently laboring under the delusion that they are cured themselves when as a matter of fact, latent germs exist within their own bodies.

The Pubescent School-Girl.—Dr. Wm. Edgar Darnall of Atlantic City, N. J., read a paper upon this subject in which he dwelt upon the great importance of the period of puberty in girls. The average girl at puberty is at school and under the modern high pressure system is straining every effort to keep up with her duties and using up all her vitality in mental pursuits. Her physiologic processes make even greater demands on the girl than those of the boy do on him. In addition to performing the same work as her brother in school, she is also expected to acquire the accomplishments, such as music and painting at an early age when she ought to be out in the open air. These years are very needful for the perfect development of the sexual organs, and the woman's whole future health and happiness may hang upon the result. Hysteria, irritability, neurasthenia, and sexual incompetency are the outcome, and the girl although bright, intelligent, and accomplished, perhaps enters life the possessor of a large outfit of headaches, backaches, and other evidences of physical unfitness. Painful menstruation is the bane of the existence of the school-girl. Chapman thinks fully seventy-five per cent. who have reached the pubescent age would give a history of painful and scant menstruation. Engelmann tabulated five thousand cases and found about sixty-six per cent. with more or less menstrual suffering. The fact of the pains being increased with hours or intensity of study, with worry and emotion, and being diminished or ceasing entirely without treatment of any kind during vacation, is a fitting commentary on the underlying causes. The girl's life during the oncoming of puberty should be carefully watched, and her studies restricted if necessary; in some cases she should be taken from school altogether for a year. Especial attention should be paid to properly regulating the functions of the bowels and bladder. All stimulants and excitements, late hours and children's parties should be prohibited. Plenty of sleep should be had by them, proper diet supplied and the habit of eating between meals forbidden. Undue excitement, mental worry or anything that may divert the vital forces from the great work they are performing in the development of a perfect woman should be jealously guarded from the pubescent girl, as this short period is perhaps the most important to her future happiness.

Speech as a Factor in the Diagnosis and Prognosis of Backwardness in Children.—Dr. G. Hudson Makuen of Philadelphia said in this paper that speech is a tool of the mind. Children are dependent upon good speech for the normal development of their faculties. The best method of arriving at an approximately correct prognosis in cases of backward children is to apply the speech test, or, in other words, to ascertain by careful study and experiment to what extent the faculty of speech may be improved. It will be found usually that those who are susceptible to training in what may be called the refinements of speech are the ones who gives promise of the best results and that the possibilities for general improvement will be proportional to the capacity for speech development.

Physical Culture in Children; the Objects to be Obtained.—Dr. J. Madison Taylor of Philadelphia read an important paper upon this subject. It should be clearly understood at the outset, he said, what is meant by the term physical culture. Two objects aimed at are, first, to raise the general bodily efficiency of the child as found in the schools by aiding the natural spontaneous processes of growth and development, both mental and physical; and, second, to assist in improving the conditions of those who are found to be below par in any direction and bring them up to the standard for their age and conditions, so that they may progress in the same degree as ordinary individuals. It is essential that all school-children should have the benefit of skilled medical supervision during their growth. Defects in the organs of special sense, notably the eye, ear, and nasopharynx, may be enumerated as some of the causes and must be dealt with by the specialist. Relatively local disorders are capable of producing great functional disorder when the physique is a little below par, whereas, if the general mechanism of the body is good, they cause very little mischief. The first main object of physical culture for children therefore is to teach them to assume right normal attitudes. Physical culture teachers are usually neither physicians nor physiologists and often not good observers. A simple rule which can involve little error is to let the shoulders alone, free from tension, but keep the back straight and hold the chest as far up as possible and keep the abdomen held in. Then the arms and shoulders are free from constraint and can be moved in any direction. Almost the most important factor is the position of the pelvis which should be maintained as nearly as possible at a level. The subject of breathing is one about which many fallacies are taught. The diaphragm is a muscle of unrecognized importance and is capable of high training and development, just as are the muscles of the arms and legs. The object in right breathing is to obtain the fullest degree of elasticity of the thorax and the greatest degree of freedom.

Discussion on Prolonged Intubation.—Dr. Shurly of Detroit referred to 240 cases of diphtheria with a mortality of 60. Of this number 8 were intubated. Prolonged intubation may be classified as those cases in which the tube remains in position more than six days, ordinarily it should be removed on the fourth day. In these cases 3,000 units of antitoxin is always given immediately. Of the

eight cases intubated all recovered except one. The causes of bad results are usually traumatism or cicatricial bands. Plated tubes should not be used. Dr. Golden uses the suprarenal glands wherever there is edema.

Dr. I. A. Abt thinks the sooner the tube can be taken out the better it is for the child. It should be removed every morning, to allow it to remain in continuously causes edema, trauma, etc. His custom is to remove it in twenty-four hours if possible. There are cases in which a tube cannot be introduced into the larynx. This may sometimes be due to the fact that all of the tubes sold at the shops are not properly made.

Prevention of Pulmonary Tuberculosis in Predisposed Children.—Dr. John A. Robison read this paper. Before the discovery of the bacillus hereditary tuberculosis was supposed to be of great importance, but in the light of modern scientific inquiry infection has supplanted heredity. Direct transmission is extremely rare. Cases of tuberculosis occurring during childhood are in nearly all instances due to direct infection, so many statisticians claim, though an equal consideration of the two factors heredity and the bacillus I think must be maintained. Healthy individuals possess certain degrees of immunity to tuberculosis, as well as other infectious diseases, and this immunity is transmitted to the offspring. If one parent is tuberculous the immunity is weakened. If both parents are tuberculous, the immunity is lessened to a greater degree and there is engrafted on the progeny a cellular nutritional weakness. Children of tuberculous parents are easily effected both directly and indirectly. Preventive treatment should commence with the ancestors. The education of the people would mean the improvement of the coming generations. A child should never be suckled by a tuberculous mother. As the babe grows the diet should contain more fat. Early a state for hydrocarbons should be cultivated. Pure candy in moderation is beneficial to growing children if given after, not between, meals. Children do not drink enough water. It is a great aid to nutrition and acts as a solvent for the effete material in the body. The diet should contain plenty of nitrogenous food. The period of puberty is a critical one. Enforced ignorance of the sexual laws oftentimes allows youth to fall into vices which weaken the cellular and organic structure of their bodies.

Hygiene.—Better hygiene should be secured in our schools. Those with a tendency toward tuberculosis should choose vocations which necessitate them to be out of doors a large part of the time.

Discussion.—Dr. Wood thought that there was a great necessity for the stricter enforcement of laws regarding the marriage of tuberculous people. Dr. Work referred to the supreme importance of proper clothing. People should change their clothing as the weather changes. The two great objects of clothing are equal warmth and equal pressure. Dr. Slagle pointed out that tuberculosis begins in the stomach through the influence of impaired nutrition, with the consequent weakening of the power of resistance.

Protracted Influenzal Pneumonia in Infancy.—Dr. Frank X. Walls of Chicago in his paper stated that infants are in a high degree immuned from influenza. Influenza, however, in infants frequently runs into protracted pneumonia. Nursing children are almost absolutely immuned even though their mothers be seriously stricken with the grip. This immunity is explained by assuming that a potent antitoxin is eliminated in the maternal milk. Infants artificially fed are more susceptible to this disease as well as others. Comby reports a case of grippe in an infant only seventeen days old. Relapses among children are not rare. The symptoms often come on very much like severe gastro-intestinal infections. Later involvement of the respiratory tract occurs. Cough is at first short, but later increases in intensity until it is paroxysmal and continuous similar to that of pertussis. Breathing is rapid and hurried and jerky. More or less coryza is present in most of the cases. Oftentimes inflammation of the middle ear, rupture of the drum and discharge of muco-pus complicates matters. The sputum was examined in all cases and the influenza bacilli were demonstrated. The pneumonia was clinically lobar. The consolidation was slow in development with diffuse bronchitis over the remainder of the lung. The nervous system was signally exempt in the cases coming under the author's notice. The occurrence of an exanthem closely simulating the scarlatina rash, which has been pointed out by many authors, were wanting in the cases under consideration. A diagnosis is sometimes difficult and may easily be confounded with gastro-intestinal infections, ordinary bronchopneumonia, malaria, sepsis or miliary tuberculosis. There is no specific treatment for influenza, but the little patient should be kept quiet and be fed on a nutritious diet suitable to the digestive capabilities of the infant. Nauseating cough mixtures should be avoided. In the event of cardiac or respiratory failure, stimulation should be given as indicated. Cold applications to the skin frequently act in a happy manner in cases of threatened suffocation.

Congenital Malformations.—Dr. Carl Beck of New York presented a very interesting paper on this subject and showed numerous Roetgen-ray photographs to demonstrate the cases reported. The most frequent abnormality of the upper extremity is polydactylism. Congenital deficiencies are naturally hard of correction, but even in such cases surgery is not without resources. Eiselsberg has successfully transplanted, for instance, a toe to

the hand. The Roentgen-rays are manifestly of great value in determining just what are the conditions present.

Membranous Colitis.—Dr. Charles Douglas of Detroit, Mich., said in his paper that membranous colitis occurs most frequently in infants over six months old and less than two years. The stools resemble those of catarrhal enteritis, except in the amount of blood. The only feature which establishes a diagnosis is the appearance of the pseudo-membrane. The severity of the attack and the gravity of the prognosis are in proportion to the amount of mucus passed daily and the length of time it continues. If longer than ten days, the prospect of recovery is not good. It is rarely seen in nursing infants. A microscopic examination of the membrane shows that it is structureless and like a mass of fibrin with no mucus or epithelial cells. The cases presented showed that different bacilli have the power by their irritative qualities and the result of their toxins to form this false membrane on the mucous membrane of the bowels. It is important to recognize that the character of the food is the principal etiologic factor in the beginning of this trouble.

Case of Ureteral Calculus.—Dr. W. W. Keen of Philadelphia said that in this case the calculus was accurately located by the X-rays before the operation was performed. The patient gave the usual history of stone in the ureter and since a recent attack of scarlet fever the paroxyms of pain on the left side have been more frequent and severe. The patient was ten years old. On admission the left side of the abdomen was so painful that a diagnosis was impossible as to location of the stone, though the diagnosis of calculus which had already been made by his physician was perfectly clear. The photograph shows a calculus about one-half the size of the last joint of the little finger in the left ureter a little below the level of the pelvic brim near the bladder. There was considerable difficulty in finding the ureter at the operation as it was imbedded in a hard mass in which the ureter was apparently lost. On examination the stone was found to be dark in color with a reaction for mucin; the shell is of calcium phosphate with a trace of organic matter. On the opening of the ureter about one-quarter of an ounce of urine escaped from the somewhat hydronephrotic kidney. The ureter was packed with iodoform gauze which was removed on the second day and recovery was uneventful.

Discussion.—Dr. C. L. Leonard stated that he had skiagraphed forty-seven cases of stone in the ureter. In most of these cases the stone had been subsequently passed so that it is advisable to wait in most cases unless the stone is large rather than resort to surgery.

Dr. Clifton Scott agreed to the extraordinary value of the X-ray in these cases but thought its value was negative as well as positive. He had operated on a case diagnosed as calculus from the clinical symptoms. The diagnosis seemed perfectly clear, but at the operation it was found to be an endothelial growth and no calculus at all.

Dr. Keen referred to four cases in which he had operated for stone and the stone had not been found.

THIRD DAY—JUNE 6TH.

Diabetes Mellitus in Childhood.—Dr. A. C. Cotton of Chicago reported a very interesting case and called attention to the care with which these cases should be managed. He also pointed out the importance of examining the urine as a part of the routine practice in the diagnosis of the disorders of childhood, so rarely done by the average physician. This perhaps accounts for the seeming rarity of this disorder in young children. That heredity plays a rôle in the predisposition of diabetes, there seems to be little doubt. It seems to the writer that the inclination of many to attribute to the infectious diseases of childhood a casual relation to diabetes is not based upon careful analysis of the evidence and that the glycosuria following such diseases is usually of the transient class. The advanced case of diabetes presents a picture of extreme inanition, emaciation, muscular weakness, dry skin and hair, brittle nails, extreme irritability and extreme sensitiveness to cold, while the urinary symptoms are always present. Furunculosis and other skin lesions rarely appear in children. No routine treatment is applicable to even the majority of cases. At the present time the regulation of the diet seems to be the most important therapeutic measure. The death certificate follows hard upon the diagnosis and the rate of mortality is very high. Elimination is most important in these little patients, while they should be protected from mental strain, shocks, frights, trauma and exposure to inclement weather. The importance of an early diagnosis is evident since success in treatment bears an inverse ratio to the chronicity of the disease.

Dr. C. F. Wahrer emphasized the view that medical treatment had little or no influence on the progress of diabetes, nor could much more be expected from the diet. Both may have some effect in improving things and holding the disease in check, but not in curing it. He could not recall any cases under ten years of age which had recovered.

Albuminuria in Infancy and Childhood.—Dr. John R. Rothmell of Chattanooga, Tenn., read a paper on this subject. Diseases of the kidney in infancy and childhood are chiefly hyperemias and nephritis following the contagious diseases, especially scarlet fever Physiological albuminuria may occur at any period of infancy and childhood. It is most common between the ages of five and fifteen

years and rarely persists, while albumin in the urine does not necessarily indicate serious organic disturbance in the kidney, yet its presence, however slight, commands the utmost watchfulness and care. Albumin is found in the urine after a rich meal, heavy muscular exertion, intense emotion and cold bathing. Even when every other constituent of the urine is normal and functional albuminuria can be differentiated, yet these cases require the most careful consideration, for sooner or later, it may be after months or years have passed, grave lesions may show themselves and we wakes up to the fact that insidious degeneration has been going on in the meantime. It is very important, therefore, to decide whether the albuminuria was simply functional or due to organic change. The prominent symptoms are albumin, high specific gravity and edema. These symptoms are especially found in interstitial and chronic parenchymatous, active hyperemia, catarrhal nephritis, parenchymatous degeneration, passive hyperemia, and acute nephritis. In acute nephritis the amount of albumin depends upon the extent of involvement of the glomeruli, and the amount of casts depends upon the extent of tubules affected. To met the symptoms of edema and ascites and to treat them require some thought concerning the condition of the patient. When uremia exists, diaphoretics, diuretics and cathartics are indicated. Podophyllin, compound jalap powder, and other watery purges may be used. Hot baths and hot packs should be used to cause profuse sweating. Where ascites is extreme tapping is of value. For stimulation teaspoonful doses of infusion of digitalis every four hours for a child of five years old can be given.

Diagnosis of the Backward Child.—Dr. A. W. Wilmarth of Chippewa Falls, Wis., read this paper. He said the estimate of mental strength must be formed from the power of attention, the strength of memory, the efficiency in the method of reasoning which comes to us all instinctively in our early days, and which is known as "common sense."

Plea for the Backward Child.—Dr. C. F. Wahrer of Fort Madison, Iowa, contended in his paper that the very bright child is taken as a standard of comparison instead of the medium child. There is often nothing the matter with the child who is considered slow. His powers are latent and may be really developing in a direction different from the course expected. It is not how early, but how well a given person develops and how effective are the results of his development.

Hygiene of Early School Life.—Dr. J. Noer of Stoughton, Wis., insisted on a more active control of school curricula by physicians and the impossibility of advantageously subjecting all children to the same physical and educational rules.

Discussion.—Dr. Work thought that the cry that came up from all parts of the country proved that there was something radically wrong with the school system and it was not confined to any one locality. The classification of scholars should be according to their intellect and schools should be selected for children which were fitted to their needs. He was particularly impressed with some of the facts brought in Dr. Darnall's paper with regard to the close-fitting and often unhygienic dress of the girl. The two important factors in all dress are equal pressure and equal warmth. Another most important factor is the food of the child which often is badly and carelessly prepared. Regular habits should be taught the child with regard to baths, elimination, eating, etc. Every child should be taught what the organs of the body are, and for what purpose they are intended, and how they should be taken care of and how they may be injured. If a child goes to school without a proper evacuation of the bowels or bladder, he cannot study properly. His intellect is dull and clouded. If a child does not have plenty of water to drink, his mind will be more or less affected from the lack of it. The greatest trouble in most of the schools is not so much with the school or with the child. It is because there are not trained mothers who understand these things themselves to teach the child at home. The duty of the profession is to educate the mothers of the community how to take care of the health of school children.

The officers elected for the ensuing year were as follows: H. H. McClannahan of Omaha, Neb., Chairman, and Frank X. Walls of Chicago, Secretary. The Section chose as their two delegates Dr. A. C. Cotton and Samuel W. Kelley.

BOOK REVIEWS.

Obstetric and Gynecologic Nursing. By Edward P. Davis, A.M., M.D., Professor of Obstetrics in the Jefferson Medical College, Philadelphia, and in the Philadelphia Polyclinic; Obstetrician and Gynecologist to the Philadelphia Hospital, etc. Illustrated. W. B. Saunders & Co., Philadelphia, 1901.

This is a general treatise on the subjects named in the title, although the author declares in the preface that the book was prepared for the training schools of the Jefferson and Philadelphia Hospitals. It is written in the author's characteristic flowing style and is easy reading. The following subjects are briefly elaborated: The Nursing of Normal Pregnancy, Nursing in the Complications of Pregnancy, Descriptions of and Preparations for Labor, The Duties of the Nurse During Labor, The Lying-in Period, The Newborn Child and Its Care, The Accidents of Pregnancy, The Accidents of Labor, Obstetric Surgery, Puerperal Sepsis, Feeding of Infants,

Disorders of Infancy, Gynecologic Nursing in all Its Phases, etc.

A nurse of average intelligence who has had a general training will find the book full of valuable hints and suggestions. The nursing requirements of obstetrical and gynecological operative procedures are clearly elaborated and sufficient description of the anatomy of the parts and technic of the operation is given to enable the nurse to do her work intelligently. In the Appendix will be found a concise and suggestive dietary and a valuable guide to the sterilization of surgical supplies and requirements for operation. The book is invaluable to the obstetric nurse and full of suggestion to the general practitioner. Its influence will certainly tend to raise the standard of aseptic obstetric nursing. The book is attractive and instructive. It should be in the hands of every nurse who is aiming to accomplish the best that the science and art of nursing can suggest.

MANUAL OF DISEASES OF THE EAR. By THOMAS BARR, M.D., Lecturer on Diseases of the Ear, Glasgow University, etc. Third Edition, Revised and Partially Rewritten. With 236 Illustrations. James Maclehose and Sons, Glasgow, 1901.

BARR'S Manual is deservedly called into a third edition. The author has adhered to his original plan and with good reason, making few emendations and these to good purpose. Effective use is made of paragraphs with smaller type for subdivisions which could not well be omitted. "The Treatment of Intracranial and Vascular Complications of Purulent Disease of the Middle Ear" and "Malignant Disease of the Middle Ear" are the subjects of two new chapters, the first of which especially was needful to bring the work in touch with the present state of advancement in brain surgery.

The copious index, the bibliography, the profuseness of illustrations, the black line titles to paragraphs and the handy size and completeness of this manual, make it one of the most available of books on the ear for students and one of the most delightful for casual reading.

A MANUAL OF DISEASES OF THE NOSE AND THROAT. By CORNELIUS GODFREY COAKLEY, A.M., M.D., Clinical Professor of Laryngology in the University and Bellevue Hospital Medical College, New York, etc. Second Edition, Revised and Enlarged. With 103 Engravings. Lea Brothers & Co., 1901.

THIS attractive little manual urges itself into a second edition after the lapse of but two years since the issue of the first. The make-up is excellent in type, leading, illustrations, arrangement, index, etc. The book is not ambitious, making no pretence to fill the place of the several treatises which recent years have given us. It seeks, however, to give in few words the most important salient facts relating to the anatomy of the parts treated and the diagnosis and treatment of their diseases. The new chapter added on Affections in the Respiratory Tract Occurring in the Infectious Diseases partakes of the same elemental character as the remainder of the manual. For students such a work may be all that could be mastered. It is very likely more than the average practitioner is acquainted with in detail. Although it lacks the fulness which one wishes to find even in a manual, it does not lack in freshness and up-to-date methods and facts, and therefore deserves to travel on its merits along with the larger works.

THE ACUTE CONTAGIOUS DISEASES OF CHILDHOOD. By MARCUS P. HATFIELD, A.M., M.D., Professor Emeritus of Diseases of Children, Northwestern University Medical School; Professor of Diseases of Children, Chicago Clinical School; Attending Physician Wesley Hospital. Chicago: G. P. Engelhard & Co., 1901. Pp. 135.

As stated in the preface, this handy volume is a "composite" of the various writers on the subjects discussed, especial pains having been taken to embody the views of later French and German pediatricians. The diseases considered are scarlatina, measles, rötheln, parotitis epidemica, pertussis, varicella, variola and la grippe. A brief space is devoted to the history, occurrence, etiology and prophylaxis, but the main portion of the work dwells on the clinical manifestations and types, the pathology and the treatment. By careful selection from the mass of literature, the author has made this a very readable and concise treatise on these important subjects. His own ideas of treatment are outlined, but are always accompanied by a fair statement of the methods employed by other American and foreign authorities. Under scarlatina Class' cocci are described, but very poorly illustrated; and, among other things, salol is given a prominent place in the treatment of smallpox. The book is handsome enough for even a bibliophile, but for the busy practitioner its uncut edges are only troublesome.

BOOKS RECEIVED.

The MEDICAL NEWS *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* MEDICAL NEWS *will shortly appear.*

ESSENTIALS OF THE DISEASES OF CHILDREN. By Dr. W. M. Powell. Third Edition by Dr. A. Hand. Saunders' Question Compends. No. 15. W. B. Saunders & Company, Philadelphia and London.

ATLAS AND EPITOME OF OPHTHALMOSCOPY AND OPHTHALMIC DIAGNOSIS. By Dr. O. Haab. Edited by Dr. G. E. de Schweinitz. 12mo. Illustrated. W. B. Saunders & Company, Philadelphia and London.

THE DISEASES OF NUTRITION IN INFANTS.[1]

BY T. M. ROTCH, M.D.,

OF BOSTON;

PROFESSOR OF DISEASES OF CHILDREN IN HARVARD UNIVERSITY.

I HAVE been asked to make a few remarks introductory to the general subject of diseases of nutrition in infancy. There is a group of diseases which occurs so essentially in that early period of development designated empirically as infancy that it may be considered to be characteristic of that period. This group consists of four diseases, infantile atrophy, infantile scorbutus, rachitis, and osteomalacia. Of these diseases infantile atrophy and rachitis are essentially morbid processes occurring during the first two years of life. Infantile scorbutus, also, while having its counterpart in the scorbutus of a later period of development both in its pathology and its treatment, shows in its symptoms and course such a characteristic picture in the middle period of infancy that it may be considered at least as being a special form of scorbutus. While it is necessary to include osteomalacia in the diseases of nutrition of infancy, it, unlike the other three diseases, only occasionally occurs in childhood and is more a disease of adult life. It, however, at times so closely simulates rachitis in its manifestations that it should be included in the group, but it is not a disease characteristic of infancy as is the case with the others.

The etiology of this entire group is very obscure, but each member of the group has its own peculiar manifestations which separate it from the others. When classified under one head they clearly present a picture of a vice of nutrition.

This group of diseases is assuming a more and more important position among the morbid conditions belonging to the early years of life as it becomes evident that it is more far-reaching in its effects and influences to a much greater degree all the diseases of early life than was in former years thought possible. Thus, the prognosis of all those diseases which have a definitely determined etiology is markedly graver where such diseases occur in an infant who is suffering from one of these general disturbances of nutrition, and in this way especially both rachitis and infantile atrophy have come to play a great and important rôle in our study of infantile diseases in general and in their therapeutics. If we consider the high mortality of these diseases when uncomplicated and the greatly increased mortality of all diseases which are complicated by them, and if we recognize that these diseases are closely associated with improper food and hygiene, it becomes evident that the proper therapeutic management of this group of diseases is of very great importance and should demand especial study and care in the feeding during the early months and years of life. There is no doubt that if less attention were paid to the use of drugs in the various non-organic disturbances of the gastro-enteric tract in early infancy and a more enlightened method of feeding were adopted by laymen and physicians, or rather by laymen through the influence of the more intelligent and advanced students of this subject, it would be possible to eradicate this entire group from its place among the various pathological conditions of early life, and thousands of lives would easily be saved where they are now recklessly thrown away. The present conditions are explained by the strong position which theoretical ignorance holds in comparison with that practical and scientific knowledge which exists and is only waiting to be received and to be given a fair trial in order to prove its wisdom and success. The field for purely dietetic treatment is an immense one, and when it has completely supplanted the older methods one of the first results will be to remove the causes of these nutritive diseases, blot them out from our nomenclature and make their pathology a museum relic of the past.

It is, therefore, well worth the time and thought of this Medical Section of the Massachusetts Medical Society to discuss in detail the different members of this protean group of diseases. A thorough knowledge of the diagnosis and treatment of each one of them is of vast importance to us, who, while our mission is to cure, still hold as the highest object and aim of our art the study and practice of prophylaxis.

The three important members of this group of diseases, infantile atrophy, infantile scorbutus, and rachitis, will receive attention later, while the fourth, osteomalacia, can be described in a very few words.

Nothing definite is known about the etiology of osteomalacia and it is simply spoken of in connection with diseases of nutrition on account of its resemblance to rachitis. There is according to Ziegler an absorption of lime

[1] Read before the Massachusetts Medical Society, Boston, June 11, 1901, in introduction to the general subject of "Diseases of Nutrition in Infants."

salt, beginning first at the medullary cavity and proceeding outward. The epiphyses are not notably affected by the continuance of the absorptive process. The cortical bone becomes spongy and decalcified, and in the severest cases there may remain little but marrow and periosteum. The opinion is generally held that in osteomalacia the layer of osteoid tissue results from decalcification, while in rachitis a similar layer represents a new growth deficient in lime salts. The periosteum is likely to be thickened and vascular, and the medulla resembles that in infancy in its gross appearance. Spontaneous fractures and various distortions may occur in osteomalacia and the thorax is flattened laterally.

The treatment of osteomalacia is the same as that of rachitis and is essentially dietetic and hygienic. In regard to the diet, the special age and development of the individual should be considered. Care should also be taken not to force into use the functions of digestion and absorption, but to allow them to develop gradually until at the time indicated by Nature they are ready normally to assume charge of the especial elements of the food which it is their peculiar province to digest and assimilate.

THE MEDICINAL TREATMENT OF SUMMER DIARRHEA.

BY THOMAS S. SOUTHWORTH, M.D.,

OF NEW YORK;

ATTENDING PHYSICIAN TO THE NURSERY AND CHILD'S, MINTURN AND RANDALL'S ISLAND HOSPITALS; PHYSICIAN TO THE DISPENSARY OF THE BABIES' HOSPITAL.

THE acute gastro-intestinal affections among children during the heated term are of three distinct types and differ widely in their variety. They are (*a*) diarrhea caused by inability to digest unsuitable articles of food; (*b*) diarrhea resulting from bacterial action in tainted milk; (*c*) cholera infantum, an intense, fortunately rare, and often fatal type, probably also due to milk infection.

The first class, the digestive diarrheas, if treated early by prompt evacuation of the offending substances and rational feeding tends naturally to recovery. Although milk is not here the source of the trouble, unless the history of the case points conclusively to some other substance as the offender, it is safest as a general rule to withdraw milk for a time. Success in the treatment of the second class, that of milk infection, depends in a large measure upon the promptness with which milk in all its forms is stopped and rigidly excluded from the patient's diet and the promptitude with which any vestiges of its residue are evacuated from the intestines. Those who now recognize this fundamental principle and act upon it rarely lose their patients from summer diarrhea. The argument is a simple one. If bacteria capable of multiplying and producing dangerous toxins are introduced into the body in milk, the latter should be cleared out and no more introduced until the bacterial brood has been exterminated and the system allowed to recover itself. Could all these cases be seen early and so protected, the subject of treatment could be covered in a few words, but this unfortunately is not always possible.

Speaking broadly, milk including breast milk, should be stopped in all cases of summer diarrhea in children under two years of age which begin with vomiting or temperature, for during this period of infancy milk constitutes the basis of their usual food and is most liable to be the source of disturbance. In its place we may give dextrinized barley-water,[1] rice-water, egg-albumin water[2], mutton-broth, beef-juice and a sufficiency of plain boiled water, if there be thirst. One of the first three of these may be offered at the usual hours of feeding, not oftener than every two or three hours, and, unless there be vomiting, in about the quantity previously taken at a meal. In case of vomiting the stomach should be allowed to rest as far as possible for twelve hours.

The truly medicinal treatment should be begun by a thorough action on the intestinal tract to remove decomposing and fermenting materials and all milk residue. So important is this that, even if the bowels have been acted upon by the usual remedies, they should be repeated if any milk has been given since the laxative was administered. Castor oil and calomel in divided doses are useful and have their own individual advantages. Castor oil hurries through the bowel the residue of undigested food and in its passage exerts a soothing influence upon the intestinal mucosa. It is especially valuable when there is much mucus in the stools. Nausea and vomiting, so often a concomitant in these cases at the outset, may, however, almost preclude its use. In such cases calomel in divided doses, gr. $^1/_{10}$ to gr. $^1/_6$, every half hour or hour till one grain or possibly more has been taken, acts distinctly as a stomachic sedative as well as an efficient laxative. Furthermore, calomel acts as a local disinfectant in the bowel and, by stimulating the hepatic secretion, brings out the aid of this most important agent in digestion and absorption. Given in these small doses it is rarely, if ever, necessary to follow it with salines, a custom which grew out of the fear of producing salivation after the administration of massive doses.

In many cases, when the patient is first seen, the process has already existed for some time and marked pyrexia with more or less prostration is present. It is not the diarrhea or the pyrexia which kills; it is the intestinal toxemia. At such a time it is wisest to lose no time by waiting for the action of laxatives given by the

[1] Barley flour, two tablespoonfuls water, one quart; cook fifteen minutes; when cool enough to be tasted add one teaspoonful Cereo, strain, salt and place on ice.

[2] Stir white of one egg into one pint boiled water (cooled), strain, salt and place on ice. May add brandy, one dram.

mouth although these should be administered in every case, but one should at once proceed to remove the source of the toxemia by irrigation of the bowel. Promptly performed this is often a life-saving measure. A large douche-bag or can is filled with saline solution (common salt, 3i to the pint) and a firm all-rubber catheter not smaller but preferably somewhat larger than an ordinary lead pencil is attached. An elevation of three feet is sufficient. The choice of temperature depends upon the degree of pyrexia. If high and the patient is not in collapse the water may be cool and will directly aid in reducing the fever. Otherwise it should be lukewarm. Allowing the fluid to flow while the oiled catheter is introduced distends the tube and also the bowel in advance of the tube, facilitating its introduction without doubling. To be effective the catheter should extend above the relatively long sigmoid flexure into the descending colon. At least four quarts should be used for the irrigation. The excess of fluid will escape in gushes beside the tube. This procedure far from being a severe one is soothing to the child and is often followed by restful sleep. It may be repeated once or twice a day. If there be blood in the stools we may add a teaspoonful of tannic acid to each quart of saline solution. Every practitioner who deals with children in summer should carry a suitable catheter with him to avoid delays. Vomiting which does not cease spontaneously calls for washing out of the stomach with plain boiled water to which, if there be much acidity, bicarbonate of soda may be added in the proportion of a teaspoonful to the quart. If the toxemia be properly controlled by the above measures bismuth subnitrate is the most satisfactory drug for internal use. It should be given in not less than 10-grain doses every hour or two hours. Its efficiency is often enhanced by adding to each dose one grain of salicylate of bismuth which increases the disinfectant power. The late J. Lewis Smith invariably used some one of the varied preparations of the digestive glands in prescribing for this class of cases. The accompanying impairment of stomachic digestion which tends to allow the passage of partially digested food through the pylorus into the intestine renders this suggestion a most rational one, worthy of general adoption.

Increased peristalsis resulting in frequent evacuations is a symptom which should be considered and treated entirely by itself. When it is advisable to check it opium best serves our purpose. It should always be given separately and not combined in mixtures, for if so combined it cannot readily be stopped or reduced in dose without affecting the other medication. Marked pyrexia contra-indicates its use and it should not be given until the bowels have been thoroughly cleared. It has been said that it would be as sensible to seal up a discharging abscess and congratulate ourselves on its cure as to lock up in the bowels the toxic products which nature is striving to throw off. Paregoric, in 10 to 15-drop doses, owes some of its efficiency to the camphor which it contains. Dover's powder, in ¼ to ½-grain doses, is a favorite probably because of the complementary assistance given by the ipecac to the regulation of intestinal secretion.

In the severer type of cases in which the stools are frequent, profuse and watery, where the patient is threatened with collapse and gastric absorption in abeyance or prevented by repeated vomiting, the hypodermic use of morphine sulphate, $^1/_{100}$ grain for a child one year of age, not only acts upon the peristalsis, but steadies and strengthens the pulse. This dose may be repeated if necessary after one hour. With this should be given atropine sulphate, $^1/_{800}$ grain, which also meets important physiological indications. Where the loss of fluid is very great and cannot be made up by ingestion, high saline enemata should be given, or, if not retained, saline hypodermoclysis should be boldly performed. (Salt, 3i, to water, Oj, boiled and strained.) Persistent high temperature, with nervous symptoms, calls for repeated cool sponging or bathing and the use of the ice-cap. Collapse must be met with mustard baths or packs, hot bottles and hypodermatic stimulation.

A tendency to rather frequent stools may persist after the acute symptoms have been overcome and the child is being cautiously led back to a simple dietary. For these Dover's powder is very satisfactory and tannalbin often useful, but even better at times is the following mixture.

℞ Pepsinæ ..... gr. j
Acid hydrochlor. dil..... ♏ jii
Glycerini ..... ♏ jiii
Aquæ menthæ pip..... 3ss
Aquæ ..... 3 j

Sig. In water four times a day after food.

Stimulants are often required during the acute stages. Brandy in 10 to 30-minim doses may be employed well diluted or added to one of the substitute foods. Preparations like liquid peptonoids which combine both nutritious and stimulating properties are most useful in 1-dram doses given with the food at each feeding, and children who receive them bear, with less loss of weight, the simple forms of fluid nourishment which must be continued for forty-eight to seventy-two hours until the acute symptoms have subsided.

In breast-fed infants nursing may usually be resumed at the end of twenty-four hours, the breast being given for half the usual length of time at every second feeding and alternating with the previous bland fluid food. The moment when one may cautiously return to a cow's milk diet must necessarily be determined by the indications in the individual cases. It is safe to say that under the stimulus of parental anxiety this return is often made

too early and too rapidly. When the appearance of the stools, allowing somewhat for the difference in the food ingested, has improved in color and consistency, and the symptoms and general appearance of the child indicate a return of more normal conditions, cow's milk may be cautiously added to one of the previous foods.

At first it is wisest not to exceed a proportion of a dram to the ounce (1-8), and often with young infants still less. As this is shown by the stools to be digested, a further increase may be made from time to time until after the lapse of several days the child's food approximates its usual proportions. It is most important not to overtax the impaired digestion and to this end we may best allow the child's appetite to remain a little in advance of the strength of the food supplied. Recovery from a sharp attack of summer diarrhea is a slow matter and extreme care should be exercised for ten days or two weeks at least. Some children, moreover, do not again recover their former digestive powers until the advent of cool autumnal weather, and must be most carefully guarded in their diet lest they develop other acute attacks which may lead to an ileocolitis or a condition of chronic intestinal indigestion.

47 West 56th Street.

THE HYGIENIC TREATMENT OF SUMMER DIARRHEA OF INFANTS.

BY HENRY C. HAZEN, M.D.,
OF NEW YORK;
VISITING PHYSICIAN TO THE NEW YORK INFANT ASYLUM.

THE frequent occurrence of summer diarrhea among young children in New York and other large and crowded cities and the high mortality-rate resulting from it are appreciated by a study of the vital statistics of the Board of Health. The reports of country districts show no such increase in the death-rate in spite of similar climatic and barometric conditions. One can readily see from these reports that the child should, if possible, spend the heated term in the rural districts. This is, of course, in the majority of cases out of the question, and I will here suggest some of the hygienic measures which will render the child less liable to contract the destructive disease, or, if acquired, will at least render an attack less severe.

Summer diarrhea has been proved to be of bacterial origin, and it is through the agency of these bacteria and their products, toxins, the growth of which is favored by improper food supply, impure air, and insanitary environments, that so many little ones succumb to it. But, first we must appreciate the fact that many children are rendered susceptible to an acute attack of enteritis by a pre-existing condition of indigestion or of intestinal catarrh. The stools should be examined, and, if necessary, the food modified as indicated. The child should not be given an excessive proportion of fats or proteids, nor should it be fed too often or too abundantly. This latter condition commonly occurs through the anxiety of the mother that the child should thrive. The first indication of rachitis should be noted. In other words, as warm weather approaches, special care should be given to the feeding of the child; thus we may avoid predisposing causes, and should the child be attacked by the disease, the prognosis will naturally be better.

In regard to the food supply, if the child is nursing, and digestion is impaired, the mother's health may demand attention. If the child is bottle-fed, the milk supply should be of the best quality possible. The control and regulation of the sale of milk by the Board of Health has saved many thousands of infants' lives, by giving a fresher and a better milk. Nevertheless, the distant source of the milk supply and the resulting delay in forwarding it necessitate an elapse of from twelve to twenty-four hours before the consumers receive it. With milk at this age, the danger of lactic acid, the multiplication of bacteria, and other fermentative changes may be considerably lessened if the mothers are shown—I mean shown by actual demonstration—how to sterilize it and how to keep it sterile.

The purchase of bottled milk rather than of milk kept in bulk in grocery stores is most desirable, and I never fail to insist upon this among the poorer families, where it is the rule rather than the exception to patronize the corner grocery. We must show that the food for artificially-fed babies should be prepared with the closest attention to directions; that the bottles and nipples, and all utensils used in preparing the food, should be selected with care and kept scrupulously clean. The only nipple that should be used is one that fits over the neck of the bottle—no connecting rubber tubing is permissible. After use the nipple and bottle should be put into water to soak, and then boiled in a solution of bicarbonate of soda. An ample supply of both bottles and nipples should be kept on hand, to allow sufficient time for this process.

The food should be given at regular intervals. It is well for the child to be allowed to drink frequently of cool water that has been boiled. Often a child cries when it is thirsty, and the mother believing it to be hungry gives it food and thus overfeeds it. If the child does not vomit the surplus food, it may collect in the intestines, cause irritation, and produce the diarrhea.

The potency of unhygienic conditions as a joint factor in producing this summer diarrhea, is also entitled to our careful consideration

in the treatment of each patient. Many suggestions can be made as to the sanitary environments, which will contribute to the welfare of the child. The room should be selected so that at some period during the day, it is exposed to the beneficient effects of the sun, and we must see that it is kept perfectly clean and well aired, and its furnishings as well.

Only those who are in attendance on the child should be permitted to remain in the room. Often in visiting among the poorer classes, we will find the sick room filled with neighbors and friends, and it will be close and foul smelling from the overcrowding. Absolute quiet is essential. We know how often a loud or startling noise will cause a convulsion in a weakened child.

All garbage and refuse should be immediately disposed of, and it should not be allowed to collect in heaps out-of-doors, where it so readily decomposes in hot weather. The effluvia from this alone not infrequently causes diarrhea in young children. Should we notice noxious odors for which we can not account, we should have the plumbing inspected and active search instituted.

The little patient should be placed on a comfortable mattress—not, as so often seen, on a hot pillow in its carriage. The clothing should consist only of a light, *white,* loosely woven, woolen shirt, a loose, light robe, and diaper. Socks are not advisable. The lower extremities and feet, in severe cases, may demand artificial heat. The napkins must be immediately changed when soiled, and washed, boiled, and thoroughly dried before used again. All superfluous clothing must be removed from the vicinity of the child. The sheets and bed coverings should be changed and aired frequently.

I believe that the use of water internally and externally is far too often neglected. A bath by tub or sponge, with use of a good soap, given daily, is essential not for cleanliness alone, but to aid diaphoresis. Bathing, by sponge, at intervals during the day refreshes the child and may supply to a slight degree the great loss of water caused by the evacuations.

The facilities that New York and some other cities offer for various long and short trips upon the water afford great assistance to the physician in his treatment. Many cases that have seemed desperate have recovered by removal from the city by water. The daily excursions of St. John's Guild have saved and prolonged many lives. The recreation piers recently built by the city offer advantages that are not to be neglected. We should also utilize the many parks, where the child may be carried for a portion of the day, and given a substitute, though perhaps a poor one, for the country.

66 West 56th Street.

AFTER TREATMENT OF SUMMER DIARRHEA OF INFANTS AND CHILDREN.

BY WILLIAM M. TAYLOR, B.S. M.D.,
OF LA GRANGE, KY.;
LATE RESIDENT PHYSICIAN IN THE NEW YORK INFANT ASYLUM.

IT is difficult to lay down any fixed rule by which we may be guided in the return to a more ample diet after the acute symptoms of an attack of summer diarrhea have subsided. It is best to be guided by the desire for food, the condition of the intestinal tract, as shown by the number and character of the stools, disappearance of abdominal tenderness and tympanites. The character should be ascertained by the personal attention given by the physician to the passages, for one can never gain an accurate idea of the true condition without investigating as to the color, consistency, the presence of mucus, curds and undigested particles of food. It is absolutely necessary that we ascertain whether the derangement be an enteritis or colitis, for in the former condition as evidenced by the thin, watery, yellow or greenish passages, we must withhold food; but in the latter, as shown by more consistent and mucosanguineous stools, we may give an easily digested diet, carefully avoiding an excess of sugars and fats, thus preventing sour acid stools which aggravate this condition.

A patient can not be safely considered and treated as convalescent from summer diarrhea until there has been an improvement in the character and number of stools and a disappearance of the abdominal tenderness, tympanites and fever. With the subsidence of these symptoms comes a brighter facial expression and a desire for food is shown. But we can not be guided entirely by the absence of these acute symptoms. Not until this condition has continued for several days or a week, with the patient on a light diet, showing that the alimentary tract has resumed its working capacity may we venture on a radical increase in the diet. Violations of this precaution we often see illustrated in cases suffering from relapses, due to a too early feeding which may not have been contra-indicated as much by the immediate symptoms present as by the fact that the system was just reacting from the wear and tear of the recent disturbance and was yet unable to undertake the full performance of its digestive and assimilative functions. The question of properly deferring a return to normal diet often taxes the ingenuity and patience of the physician.

The after-treatment of this condition is essentially hygienic and dietetic. Even after all immediate symptoms have subsided it becomes a serious question as to what food shall be used. Of the various kinds of prepared foods, I think the most satisfactory is the pure modified cow's milk, using as a diluent, barley-water previously dextrinized by a diastase or

maltine. By beginning with a percentage milk, a food that will agree with the child is almost invariably attainable. The tendency is to begin with too high a percentage, for it is noticeable in changing the diet of any child that its digestion will be disturbed at the first feedings by an amount which will later be taken without the slightest ill effects. A good plan is as follows: Decide upon the number of feedings, amount of milk, sugar, cream and diluent to be taken by the child. As, for example, we would take three ounces of whole milk, one dram each of sugar and cream and three ounces of barley-gruel. Seven feedings of this amount and proportion may be given in twenty-four hours. To prepare the barley-gruel, add two full tablespoonfuls of barley-flour to one quart of water and boil for fifteen or twenty minutes; to this is then added two teaspoonfuls of Cereo, or dextrinize the barley-water with any other reliable preparation on the market. The diastase partially digests the starch of the barley-water causing it to form with the milk a much looser and softer coagulum. This is shown by actual experiment in the laboratory and also in the curdled vomitus of children taking milk thus modified, the curds being softer and less tenacious than the firm, ropy curds which are almost invariably present when such diluents are used without diastase. Wheat or oatmeal flour may be used instead of the barley flour in making the gruel, though from my experience I favor the latter. This is a simple method of preparation and one in which the proportions may be easily modified. Any mother may be instructed in its preparation so that there will be little chance for error.

If the above treatment fails, kumyss in my estimation stands next. The dislike for kumyss manifested by some is usually overcome after the first few feedings, though it is sometimes more readily taken if one part of water be added to four parts of kumyss. I have seen patients with whom it seemed that all else had failed, begin to improve immediately when put on this. It is especially well taken during the summer months, having a cool, pleasant taste and a fondness for it is soon developed. Beef-juice given three times daily is a most valuable aid in the condition under consideration, seldom, if ever, causing intestinal disturbance and being easily assimilated. This should be expressed from fresh, lean beef daily, thus having it perfectly sweet and fresh. A good method for giving it is one dram to an ounce of barley-water.

In the dietetic treatment during this stage, milk of course, should form the principal factor, but children of two or three years of age will not always submit to a milk diet, nor is it best to keep them on it. They may have in addition beef, mutton, or chicken-broth from which the fat has been carefully removed. Finely chopped or scraped rare roast beef is also a valuable addition. However, we should not rely on these broths to take the place of milk for any length of time, since upon them alone the child invariably loses ground, but they are unquestionably of value in supplementing the milk diet. Dry toast or zweibach seems the safest and best form of farinaceous food to begin with in children who are accustomed to a mixed diet, but at first a liquid diastase should be administered to aid the digestion of starch. Some form of pepsin, as the wine or cordial, is of undoubted service in the management of these cases when a mixed diet is begun.

The general condition may be favorably influenced by inunctions of cod-liver oil and they are especially indicated in children whose circulation seems sluggish, with blue skin, cold feet and hands. A most marked improvement is often seen in a short time from this treatment. The cod-liver oil should be warmed and rubbed in by the hand from the head to the feet. This should be continued for half and hour, repeated twice daily, and followed by a warm sponge bath. By the sponging the unpleasant odor is done away with and the comfort of the child enhanced. Aside from the absorption of the fats, the massage has a decidedly stimulating influence.

Cases allowed to run on without being checked early, often mark the beginning stage of serious malnutrition, anemia, chronic enteritis and mucous colitis. The tendency to constipation that sometimes occurs during convalescence is best corrected by the diet, water given freely between feedings, abdominal massage and enemata. As a rule purgatives are to be avoided unless demanded by some other condition, one dose may at times undo the good results which it has taken days or weeks to accomplish. In these cases abdominal massage should be practised five minutes twice daily; it produces surprising results, not only does it stimulate peristalsis and relieve constipation, but favorably influences nutrition. If in older children a laxative is used, fluid extract of cascara is the best and should be given daily in doses of five to eight drops gradually diminished in amount from day to day, and the best time of administration is after the last meal.

Tonics are nearly always indicated and the syrup of ferric iodide seems the best of all forms of iron tonics for children, for it produces fewer unpleasant effect than any other. It should be given in from two- to five-minim doses to a child of two years old. The tincture of nux vomica for older children is valuable in these cases of malnutrition with poor appetite and sluggish bowels, being best given after meals in two-minim doses for children of from two to three years of age.

By carefully watching for the symptoms of dentition, the nervous diarrhea so often ac-

companying it may be controlled by early lancing of the gums if swollen and painful, and by the administration of bromide of soda, about four grains every three hours for a child one year old. A cool morning sponge, the greater part of the day spent in the open air and a well-ventilated sleeping room will go far in supplementing the other treatment and in preventing relapses, so common during the summer months. Coupled with pure air comes absolute cleanliness. Careful attention should be given to excoriated buttocks and frequent sponging, change of napkins and powdering go far in preventing this annoying complication. The likelihood of producing an enteritis in one convalescent from a recent attack by sudden cooling of the body should be borne in mind in an effort to get fresh air. For the mucous colitis following this condition, daily high irrigation of the colon with normal saline solution is productive of the better results than are medicinal remedies administered with a view to local action on the colon. The exact amount of solution used is a matter of judgment, but the irrigation should be continued until all particles of mucus are removed.

THE CLINICAL FEATURES AND TREATMENT OF ACUTE BRONCHITIS IN CHILDREN.

BY CHARLES O'DONOVAN, A.M., M.D.,
OF BALTIMORE;
CLINICAL PROFESSOR OF DISEASES OF CHILDREN IN THE BALTIMORE MEDICAL COLLEGE.

BRONCHITIS is such a common disease amongst children that its clinical features should be familiar to every one, yet in many cases it produces such mild symptoms that its presence is readily overlooked. Systematic examination of the lungs of all sick children will reveal in many instances unsuspected bronchitis of varying degrees of intensity, often sufficient in itself to account for illness erroneously diagnosticated because of imperfect examination.

In a child otherwise healthy the most prominent, perhaps the only symptom noticeable will be a cough, not necessarily very severe, but due apparently to some local irritation in the throat or lungs leading to a desire to relieve the irritation or impediment by the expulsive effort of the cough. The fauces and tonsils may or may not be reddened or tinged; if true bronchitis result, as it does so often, from a direct spreading of the inflammatory process from the nasopharynx to the bronchi, then there will probably be turgescence of the fauces as well; but bronchitis may occur also as a primary disease, in which case the fauces will show no coincident irritation. This is a point of some importance as affecting another symptom, fever; for this is found to be more frequent and in greater degree in those cases in which the fauces are also involved than in cases of primary bronchitis. In the latter there may be little or no fever, and but little acceleration of the pulse, as long as the bronchitis affects only the larger tubes and is not very extensive in the matter of area involved. This limit, however, is soon overstepped, and most cases of bronchitis present more or less fever, in addition to the cough, with a corresponding rapidity of pulse-rate, and the fretfulness and irritability that appear in children as the constant accompaniment of fever. This is usually worse as night approaches, the child having been fairly cheerful and happy during the day, having had its morning nap, and played with but trifling discomfort afterward, will become quite fretful later in the day, will cough more frequently, and more harshly, as evening approaches, showing at the same time by its brightened color and hurried pulse that fever is present.

In mild cases the fever may reach 102° F. and the pulse rate run up to 110 or 120. The cough is usually worse early in the night, and may become so troublesome as to render sleep possible only at intervals. After midnight the cough will be less, as the child becomes worn out and sleeps heavily till early in the morning. Changes in the respiration follow deeper extension of the bronchitis which produces interference with the proper aeration of the blood, or a very general dissemination of the disease which produces the same effect: in mild cases the respiration will probably remain unchanged. Both lungs are usually affected at the same time, not necessarily in the corresponding portions of each lung; but the general principle holds that the invasion increases in severity or diminishes in each lung coincidently. In this respect simple bronchitis differs very materially from complicated cases; for should bronchopneumonia develop, a most common and most serious complication, the various spots of more or less circumscribed consolidation occur in different parts of each lung without any apparent coincidence, and one lung may advance toward recovery while the disease is progressing unfavorably in the other. In like manner when the pleura becomes involved in the inflammatory process, as is often the case in deep-seated bronchitis, it may readily be on one side only.

Of the various complications it is not intended to speak, for this paper is to be limited to the subject in hand, which is quite sufficient. Bronchitis in children is a disease having no definite limit. It may not advance beyond the simplest invasion of the largest bronchi, producing some roughening of the respiration with a dryness of the throat and desire to cough, or it may invade the entire area of both lungs, filling them with universal râles, dry and sibilant at first, but becoming moist and bubbling at many points as the small bronchi become loaded with mucus in the later stages of the disease. In the matter of time, there is no definite division between these stages, for they will most likely occur simul-

taneously in different parts of the child's lungs as the areas of congestion or exudation advance and recede with the varying ability of the child to resist the invasion. While there is no fixed limit to it, very much can be done by proper treatment to cut short bronchitis in children at any stage of its course. In this, as in many other diseases, the child shows its remarkable power of resiliency against the depression under which it labors. Whether it is by the elaboration of an antidote to some specific infection which causes the disease; or by a power easily recognized, but described with difficulty, which enables the organism to check the onward progress of disease and rapidly repair the damages inflicted; in either case the child possesses this ability in marked degree, and is enabled to exert it by the assistance of medicines and attention to hygiene and nutrition far more readily and effectually than lies in the power of the adult. For this reason, in children who are beyond the first year of life, uncomplicated bronchitis is rarely fatal. Very young children with general bronchitis and much secretion frequently are overwhelmed by the obstruction and become smothered, as it were, from inability to unload the bronchi. Older children are better prepared for this emergency and cough up quantities of mucus to be swallowed or expectorated according to the age of the child.

The case may have a very grave appearance and may continue for a long time, but if uncomplicated the lungs are usually quite competent to oxygenate the blood, and recovery follows after lapse of more or less time. After severe or prolonged cases of bronchitis in children it is usual to find the lungs emphysematous, the percussion note highly resonant, whistling or cooing dry râles present in various parts of the lungs, the expiration much prolonged, showing a loss of the usual elasticity of the lung. This may persist for days or weeks, according to the severity of the bronchitis or the length of time occupied by the attack, but with care and attention during the child's slow convalescence, it will in time disappear.

As soon as bronchitis is diagnosticated in a child, intelligent treatment must be compelled. No case is without danger, if not of death, at least of a long illness, with a constant fear of complications that are only too likely to result fatally. Younger children have more to dread than older ones, but every case must be cured as soon as possible. In mild cases no medicines are required; regulation of diet, a mild laxative, investigation of the child's clothing both for the day and for night, so as to provide comfortable warmth of surface at each period, and confinement of the child to a sunshiny, well-ventilated apartment, with suitable and equable temperature, will insure its prompt and complete recovery.

It is well to remember, however, that one attack of bronchitis seems to weaken the power of resistance of the child, and that exposure to ordinary conditions should be made carefully and gradually. More extensive or deeper invasion requires much more attention. In addition to the restrictions mentioned above, medicines are required. It is best that the child should be put to bed, as many unavoidable exposures to open doors or windows are thus avoided, and the rest and warmth of the bed are in themselves excellent curative measures. Babies take medicines with difficulty and are best treated by local applications and inhalations. The oiled silk jacket, more or less wadded, and made to fit close to the chest, held in position by being pinned to the napkin, or by tapes passing between the thighs, is of valuable service. Beneath this stimulating liniments, containing turpentine in the required strength, or weak mustard plasters, may be used to produce irritation of the surface, never strong enough to blister the skin. For each application the jacket is opened at the back and is replaced immediately.

Many stimulating inhalations have been proposed to promote free transudation into the bronchi, but none are satisfactory in every case. Frequent inhalation of steam often produces fluidity of the tough bronchial mucus and its ready dislodgment by coughing. This is easily administered by covering the crib with a canopy made of a sheet beneath which the kettle is boiled. The vapor of benzoin has appeared at times to be beneficial, but inhalants are of such varying effect that the long list recommended must be tried to find the one most suited to individual cases. Whatever medicine is given to infants must be easily taken and not apt to destroy the desire of the child for food. Personally, I use very few drugs in such cases, the syr. hypophos. co. in doses suitable to the age of the child being the only expectorant that I try and experience has taught me that it is beneficial. If, in spite of these remedies, the bronchi of the infant are becoming more and more oppressed with mucus, an emetic may be used, tr. ipecac, in dose sufficient to produce emesis, being the best. This is not to be given unless it is actually required, for the practice of making a child vomit every time that it has a severe spell of coughing cannot be condemned too harshly; it is necessary in these severe cases to save the baby's strength in every way, not to deplete and overtax it on slight provocation. Stimulants will be required in proportion to the fever and the manifestly weakened action of the heart; the pulse will be the best guide in this. It has been my custom to use alcohol in all of these cases and I have never seen any harm result; on the contrary, it appears to have a sustaining effect upon the heart that is most desirable, and from it can be obtained all that can be had in this direction. I have never seen any additional benefit in in-

fants from strychnine or other powerful tonics, which could not be obtained from alcohol. It is important to watch the effect of the stimulant, which is given for a specific purpose and should not be given in excess of the quantity required to do what is needed. If cyanosis is developing and the baby becomes more and more obtunded by the deficiently oxygenated blood, it should be frequently changed in position, lying on one side for a short while, then on the other; a wakeful, crying baby is to be preferred to one that becomes lethargic. Indeed, we have good authority for keeping the baby awake by severe measures, such as spanking it, or by successive applications of hot and cold douches to its chest. It is well to remember that a baby possesses latent powers of recuperation that justify, at times, treatment that would appear in an adult to be unnecessarily severe.

The same rules hold good for older children in severe cases. When the fever runs high and respiration is much impeded, confinement to bed and free alcoholic stimulation are called for; the wadded jacket of oiled silk is a great assistance. If there should be also much pain from pleuritic involvement, I am old-fashioned enough to believe that a large flaxseed-meal poultice will give more relief than any other external remedy; this is the result of observation of many cases. Inhalations are quite soothing, or, if desired, can be made to loosen the thick mucus and promote expectoration. Older children take cough syrups better than babies, and are less likely to have their stomachs disordered thereby; such mixtures should contain muriate of ammonia in proportion to the age of the child. Judgment must be used in giving hypnotics; bromide of soda will sometimes suffice to give rest to the excited nervous system, but oftener codeine or heroin will be required. In very severe cases it calls for nice discrimination to decide whether or not the child should be made to sleep, whether danger is most to be apprehended from a fatigued and overtaxed nervous system, or from deficient aeration of the blood. In such cases the inhalation of small quantities of oxygen has proven of value. In prolonged cases, when the heart action is very rapid and the organ becomes fatigued, strychnine, given, by hypodermatic injection, is of great service, The tougher muscle of the youth will respond to such treatment long after the more delicate fibers of the baby would have passed the point of final exhaustion. In every case the disease should be completely cured before the child is allowed full liberty, as imprudence is very likely to start again the process and the bronchitis may so continue for weeks or months. It is not necessary to confine the child strictly to its bed, but in cold weather it should remain indoors until the bronchial catarrh has entirely disappeared. This complete cure can be hastened by judicious feeding, the use of stimulating frictions of the chest, and by the exhibition of cod-liver oil and of small doses of iron and arsenic, if the child is anemic.

EMPYEMA.[1]

BY JOHN A. HARTWELL, M.D.
OF NEW YORK;
ATTENDING SURGEON TO COLORED HOME AND HOSPITAL, NEW YORK.

THE memory of the unsatisfactory outcome of many of the cases of empyema coming under my observation while a hospital interne led me during the past winter to study this subject as it was found in the records of the Presbyterian Hospital of this city, with the view of learning any practical points concerning its occurrence and management.

The condition is one which we, as younger practitioners may be called on frequently to treat and I have therefore thought its consideration may prove of interest and profit. The material at my disposal includes the histories of fifty-two cases, the total number found in the wards of the Hospital named during the eight years ending last July. A recital of the histories in detail could only be a tiresome proceeding and will be omitted from this paper that your attention may be called only to the conclusions drawn.

You will agree with me in asserting that the outcome of many cases of empyema not proving immediately fatal is very unsatisfactory if the picture, so often seen in hospital wards of patients presenting a pus-discharging sinus for weeks and even months after the operation, is called to mind. That such a picture is not seen in every case, nor in the majority of cases, gives the right to hope that a thorough understanding of the disease may confine it to a much smaller minority. With this idea in mind I studied the cases from the following standpoints and endeavored to draw practical conclusions therefrom: Sex, age, family and previous personal history, exciting cause, side and extent of pleura involved, character and quantity of pus with contained bacteria, the treatment instituted, including character of operation, irrigation of cavity immediate and later, the form of drainage, and mortality.

The influence of sex was found to be an etiological factor in the proportion of 38 males to 14 females, a ratio practically the same as in pneumonia which is recognized as the most frequent antecedent of empyema.

In the matter of age there is found a more practical important influence. One-fifth of the cases were in children under five years of age and more than half occurred before the twentieth year. This fact impresses the importance of ever keeping in mind the possibility of an empyema being present in any chest lesion in children and young adults. This importance will be more fully recognized when later we consider the marked advantage of an early diagnosis in just these cases.

[1] Read before the Quiz Society, New York, 1901.

In seven cases a tuberculous family history was present and in five others such a history was doubtful. The influence of this was manifest in only two cases, one patient dying and the other remaining unhealed. The effect of a tuberculous personal history could not be studied, because of the fact that phthisical cases are not admitted to the hospital. Pneumonia was present as the exciting cause in 26 cases and in 3 others it was a probable factor. In 10 cases a simple pleurisy became purulent; in one case sarcoma and in one trauma acted as exciting causes and in one—double sacculated—the infection seemed to be derived from a general sepsis due to pyosalpinx. In 43 cases the whole pleura was involved and in 9 cases the empyema was sacculated. In one case it was general on the left side and sacculated on the right and in one case a double sacculated empyema was present. The latter was interesting in that it resulted in a cure after aspiration and rupture into the bronchi, through which good drainage took place. The constitutional symptoms were as severe in the sacculated cases as in the general, except when the former were very limited in extent.

In 27 cases the right side was affected, in 22 the left, in 2 both sides, and in one the side was not stated. No influence in the course of the disease attaches to the side involved. Especial interest attaches to the study of the cases from the standpoint of the bacteriologist, for it is from him that we may hope for increased accuracy in a differential diagnosis of the varying types of the disease. The time may come when such a diagnosis will so help us that we can effect a cure in certain cases by aspiration or simple incision without rib resection, reserving the latter for fewer cases than at present we dare attempt.

A bacteriological examination was reported in 24 cases in the following proportions: In 12 the pneumococcus was found, in 8 the streptococcus, in 4 both of these, in 2 the staphylococcus, in 1 the tubercle bacillus, in 1 an undetermined coccus, and in 4 no bacteria were found. In 4 cases where pneumonia was the exciting cause no pneumococci were found. Three of these were of long standing when the bacteriological examination was made, one having a phthisis. The fourth, the only case of the kind, was acute after pneumonia. All of the 4 cases in which the pneumococcus and the steptococcus were found associated had a pneumonia as the exciting cause. The pneumococcus was the cause of the most virulent cases, the infection being even more marked than with the streptococcus and the course being more prolonged if a fatal termination did not intervene.

Death occurred in 7 cases in which a bacteriological examination was made and in 5 of these the pneumococcus was found. In one of the remaining 2 sarcoma of the chest-wall was the cause of the empyema and of death and in the other a general pyemia, with empyema only as an incident, caused death. The character of the pus evacuated gave no indication of the contained bacteria except the thin yellowish pus due to tubercle bacilli. A thick, fetid pus often gave no growth on culture media and showed no germ life under the microscope while a "sweet laudable" pus contained pneumococci and streptococci.

With this brief summary of the etiology, general nature and bacteriology of the disease, I will pass on to the more practical question of its management and a consideration of the causes of our failures. Of these a more detailed study will be found interesting: (1) When shall we operate in empyema? (2) Should an anesthetic be used? (3) How shall we operate? (4) What shall be the after-treatment? and (5) why do cases of empyema die?

The answer to the first query, when to operate, admits of but one answer and that is immediately on making the diagnosis of pus in the pleural cavity. Occasionally a case may present itself where an empyema has developed very rapidly consequent to a pneumonia and the latter has so debilitated the patient that the radical operation would be inadvisable at once, a simple aspiration being first performed. But such cases are rare and the records here considered showed that, other things being equal, the earlier an operation was done the more successful was the outcome of the case. The practical bearing of this is summed up in the injunction to make an early diagnosis. If a pneumonia does not terminate according to rule, the possibility of pus being present should be borne in mind.

The choice of an anesthetic seemed to lie with the individual preference of the operator and this preference was for chloroform in 31 cases as against ether in 13, and cocaine in 3, 5 being done without anesthesia. In the administration of the anesthetic, care was taken never to produce profound narcosis, with the idea that the empyema might rupture into a bronchus and, if the laryngeal reflex were abolished, pus might be drawn into the sound lung. There is no mention in the records of any accident occurring from anesthesia nor from the actual operative procedure.

How shall we operate? The answer to this question is given in a decided manner by a careful study of the fifty-two records. It is that the satisfactory termination of an empyema was in direct ratio to the thoroughness of the drainage established—and thorough drainage implies an arrangement by which pus is not allowed to remain pent up in the abscess cavity for even an hour after its formation. In some cases, those of children notably so, this was accomplished by simple incision. In others the resection of pieces of one of two ribs failed to provide it. In general, however, it may be said that in those cases

which were slow to heal and which produced long-continued sepsis, the opening was smaller than in the more favorable cases.

In 15 cases intercostal incision alone was done without resection, with the following results: Deaths, 6; recurrences, 4; cures, 5. Of the 5 cures 2 were in children under five years of age and 2 in patients each with a small sacculated empyema, leaving only one adult general empyema cured by simple incision against 6 ending fatally and 4 recovering. These figures may possibly exaggerate the inadequacy of simple incision, but they are so emphatic that the surgeon must give them serious consideration before deciding on the lesser operation. The fear of risking the greater operation seemed to decide the operator in many of the cases for simple incision. But the histories throughout record practically no shock as attending the rib resection—except in one case of Estlander's operation—and in many cases where the ribs were resected the patients were in a desperate condition prior to the operation.

The following rules seem good ones: In an adult remove two inches of two ribs. In a child remove two inches of one rib or one inch of two ribs, in all cases of general empyema. No distinction should be made between the very recent and the more chronic cases in the amount of rib removed, the former often being as intractable as the latter. The resection should be done subperiosteally. This method prevents hemorrhage and is rather easy of accomplishment than otherwise.

The position of the opening made is an important point. In the cases here studied the operator often made it much higher than was wise, as was afterward demonstrated by the depth of the abscess cavity below the opening as seen from the inside. In one case the peritoneum was opened, the sixth rib in the posterior axillary line being resected. This is a very unusual accident in this position and in this case no harm resulted. In 13 cases the eighth rib was resected, usually in the posterior axillary line, without mishap and in one case the ninth, with successful result. In general a rib below the seventh may be selected with safety. An exploratory needle puncture should be made prior to operation as low as the cavity is believed to extend and, if pus is found, open the pleura at that point. If not found, explore in the space above and so on till the proper point is reached. The repeated punctures are harmless if antiseptically done. The possibility of wounding an abdominal viscus should be borne in mind. The posterior axillary line proves in general the most satisfactory position for the resection.

Having removed the rib and evacuated the pus from the pleural cavity, the next question to confront the surgeon is as to the advisability of washing out the cavity. In only five of the cases here considered was such irrigation employed. The irrigation fluid being Thiersch's solution three times, normal salt solution once, and bichloride solution (1-1,000) once. This number is so limited that no conclusions can be drawn as to the efficiency of the procedure. Certainly there was no untoward result, the precaution being taken to allow the patient to partially recover from anesthesia before irrigating. This is advisable as a number of cases of alarming heart failure have been reported where such precaution was neglected, a danger particularly liable when the left side is involved. If such irrigating is a safe part of the operation there seems no reason to neglect doing it, for on rational grounds it is well to get all the pus possible out of the cavity and to get the pleura as free as possible from infection.

The choice of drain material lies almost entirely in the use of a soft perforated rubber tube, double or single. This answers all the indications and is clean. In cases which refuse to heal as well as seems desirable the substitution of gauze for the tube gives a beneficial result, the irritation by the gauze—plain or iodoform—aiding granulation.

In 22 of the cases irrigation of the abscess cavity was performed sometime in the after-treatment. In a few cases this was done regularly and continuously; in others, only at irregular intervals. The solution used was as a rule normal salt solution, Thiersch's solution, or boric-acid solution. In one or two cases very weak bichloride solution was used and in one week creolin solution.

Although the records are incomplete as to the benefit derived from such irrigations, the repeated study of the histories seem to show that it did good. In no case did it do harm or produce unpleasant symptoms except in that of a phthisical patient where an opening was forced through the pleura into the lung while the cavity was being irrigated and the fluid was expectorated. On rational grounds there seems no reason why such irrigation should not be used when we consider the existence of a large pus-producing cavity which at best is imperfectly drained and is causing in most cases constitutional poisoning. But the fact that it was only used in less than half of the cases here considered, which were treated by a number of different men, shows a general tendency against the treatment. This seems to be due to a fear on the part of the surgeons that such irrigation will produce local and perhaps general damage. These fears are not well founded. If a poisonous antiseptic is used there is not the slightest danger of general poisoning, provided the caution is taken to see that all the fluid that is put in is returned. This can be surely accomplished by a second washing out with non-poisonous solutions. The local damage can not be serious when we consider that the peritoneum may be safely sponged off with a 1-2,000 bichloride solution. Surely a thickened pleura covered with fibrinous exudate is a less delicate membrane than the peritoneum.

In any case of empyema where the discharge is large and the drainage not absolutely perfect and general sepsis is present, irrigation with a bichloride solution, 1-5,000, or carbolic acid, 1-100, is not only a safe procedure, but is one absolutely indicated and sure to result in nothing but good.

Why do cases of empyema die? Of the 52 cases here studied 12 died. Five of these died from causes other than the empyema itself, as sarcoma, general pyemia and tuberculosis. This leaves 47 cases with 7 deaths attributable directly to the empyema, a mortality of 15 per cent. Of these only 2 occurred where prompt treatment was used, the duration of one being four days and of the other five days. The remaining 5 deaths were in patients of very low vitality prior to the empyema or in those in whom the disease was neglected. From these figures it seems that with patients of fair physique, prompt surgical interference ought to bring the mortality of empyema well under 10 per cent. and perhaps as low as 5 per cent. This gives us food for reflection when we find the mortality from all statistics given by various authorities varying from 15 to 20 per cent. or even higher.

Summary.

1. Children are especially liable to empyema following pneumonia. Unless promptly relieved by drainage of pleura the prognosis is bad. With such relief the prognosis is good.

2. Pneumonia caused empyema in 50 per cent. of the cases here considered, and such cases were of severe type.

3. Tuberculous family history exerts little influence on empyema.

4. In about one-sixth of the cases the empyema was sacculated.

5. The pneumococcus was found in 50 per cent. of the cases where examination was made; the streptococcus in 33⅓ per cent.; the staphylococcus in 8 per cent.; the tubercle bacillus in 4 per cent., and no bacterium in 16 per cent. The pneumococcus produced the most virulent infection.

6. Chloroform was the anesthetic of preference. Deep narcosis is contra-indicated, owing to the danger of pus being drawn into the other lung from a ruptured bronchus.

7. In adults with general empyema two inches of the seventh and eighth or eighth and ninth ribs in the posterior axillary line should be resected. In children the same length of the seventh rib. Simple incision, with our present knowledge, is rarely advisable.

8. Operation is indicated as soon as diagnosis is made.

9. Irrigation of the abscess cavity with bichloride solution, 1-5,000, or carbolic acid, 1-100, is indicated, unless drainage is perfect and no sepsis is present. In children the solutions may be weaker.

10. The mortality from the empyema proper was 15 per cent. We may hope to reduce it to one-half that number by earlier and more radical treatment.

SEXUAL NEURASTHENIA IN THE MALE; A PLEA FOR A MORE ACCURATE USE OF THE TERM; TREATMENT OF THE TRUE FORM WITH CITATION OF CASES.

BY RAMON GUITERAS, M.D.,
OF NEW YORK.

NEURASTHENIA, while one of the most distressing conditions that comes under the physician's care, is, nevertheless, so certainly amenable to well-directed treatment that it is difficult to sympathize with the despairing or impatient attitude with which many practitioners regard it.

Oftentimes patients suffering from this trouble have made the rounds of a dozen physicians, failing in each instance to find the sympathetic consideration and the systematic examination and treatment that these cases require if a cure is to be made. It is impossible to frown down, or laugh away as purely imaginary, a condition that has produced so much wretchedness, and so much mental and moral deterioration; a condition that daily increases the population of sanitariums and asylums, and swells the list of suicides.

Whether because of its climate or because of its "strenuous life," New York has come to be regarded as a nursery for neurasthenics; but be that as it may, every physician here in active practice encounters many cases and is fully aware that they tax all the resources at his command. It is not my purpose to take up the subject of neurasthenia as a whole. On the contrary, I shall confine myself to a brief consideration of a special form, *i. e.*, sexual neurasthenia.

This variety differs from the others only in the multiformity of its symptoms, in their relatively greater severity, and in the fact that the chief source of the trouble, whether recognized or not by the patient himself, lies in some part of the genital tract. I say whether recognized or not by the patient himself, because it is necessary to emphasize the fact that this group of neurasthenics is much larger than is generally supposed.

The term is often applied loosely enough to those whose attention has become fixed upon the genital apparatus, either because of a real, or fancied lesion. It should, however, be restricted to those cases of neurasthenia in which a morbid condition of the genital apparatus exists, a condition which is demonstrated to be the source of the systemic disturbance by the fact that its cure is quickly followed by the disappearance of the neurasthenia.

The diseased condition of the genital tract may never have been suspected by the patient, and I feel justified in attempting to place the term sexual neurasthenia upon a purely histopathological rather than a psychopathological foundation, or a vague combination of the two, for the reason

that many apparently incurable cases of neurasthenia are incurable only as long as the real cause of the trouble is undiscovered. To the present lax use of the term sexual neurasthenia is due the fact that the possible existence of a lesion of the genital tract in cases of neurasthenia is generally lost sight of, except in a patient whose mind is centered upon the sexual organs as the source of his trouble.

An accurate use of the term will serve to emphasize the necessity of a thorough examination of the genital tract in every case of neurasthenia as a routine practice before attempting any line of treatment, for, not only does the commonly-accepted definition of the term cause the profession to overlook many real cases of this form of neurasthenia, but, on the other hand, cases are sometimes classed under this head which are not sexual neurasthenia at all, but which during or following some exhausting disease have developed a group of sexual symptoms dependent not upon a local lesion, but upon general systemic exhaustion. In such cases local treatment will not only be useless as a means of curing the disease, but positively harmful; since it will tend to confirm the patient in his belief that the seat of his trouble lies in his genital apparatus, while the failure of the local treatment will add weight to his despair. A careful examination in such a case of the genital tract having failed to reveal a lesion, not only will the assurance of this fact tend to shunt the patient's attention out of a dangerous groove, but the improvement that will follow a general restorative treatment will enhance his confidence in his physician and generally expedite his cure.

For an adequate appreciation of the general systemic disturbance to which a lesion of the genital tract may give rise, it is only necessary to consider the immense importance of the rôle that sexual life plays in the history of the individual and of the race, and to realize the relative richness of the vascular supply of the sexual organs and of their innervation from both the central and the sympathetic system.

It is not necessary to go into the anatomical and physiological relationship between this and the other great centers of reflex activity. Any attempt to do this would transcend the limits of a short paper, and would be merely covering the same ground that has been ably worked over by others. Suffice it to say that even a brief study of the facts will serve to destroy any illusion as to a limit in the number and variety of reflex disturbances that may arise from a disease of the genital tract. Nor is the amount of reflex disturbance any indication of the extent of the disease, or of its location.

Writers on the subject who have made an attempt to place the etiology of the disease upon a purely physical basis, have agreed in attributing the principal rôle in the causation to affections of the prostate, seminal vesicles and the spermatic cord. Although a few of the later observers admit that a lesion of the urethra may at times give rise to neurasthenia, I am convinced from my own experience that they have not given this fact the prominence that it deserves.

I have seen patients presenting various neurasthenic symptoms, some of them of the graver type, who were found to have nothing the matter with their genital tract other than a stricture or a patch of granulation tissue, or a denuded area of the urethra, and a proof that this condition was the source of the whole trouble was afforded by the disappearance of the neurasthenia after the cure of the local lesion. I will confess that the result in the first case was somewhat of a surprise to me, and not until the experience had been repeated, not once but several times, was I led to appreciate the full extent of the importance of lesions of the urethral canal in the causation of neurasthenia. These cases included not only those in which there was a distinctly sexual type of neurasthenia, but some in which the sexual element played very little part. There was, as a rule, in these latter cases a recognition by the patient of the fact that the urethra was not in an entirely healthy condition, but this was not regarded by him as an adequate cause of the depression,the dispersion of attention and the lowering of mental and bodily tone from which he was suffering, but rather as perhaps one of many contributing factors.

Before passing in review a few cases that may serve to illustrate some of the points I have tried to make, it would be well, perhaps, to attempt a brief description of the general neurasthenic state.

Neurasthenia may be defined as a chronic, functional, nervous disorder, which is characterized by an excessive weakness, and irritability of the nerve centers, so that the patient is exhausted by slight causes and reacts immoderately to slight irritation. He complains of a feeling of mental depression, he tires quickly, cannot pursue a train of thought or a single line of work for a long time, and has lost all desire for physical or mental exertion. He is more or less indifferent to everything and occupations in which he formerly took an engrossing interest are felt to be a weariness to the flesh. He has a dull, empty feeling in his head. His memory has become defective. He has lost confidence in himself, and dreads going into company. His indecision is shown in a tendency to consult others upon matters in which formerly he was wont to make out his own line of conduct with alacrity. He is fretful, peevish, and easily upset by trifling annoyances. After he has gone to bed he lies awake for hours brooding over his trouble, or passing in review the events of the day, which one and all present themselves in the most unfavorable light, and when sleep finally comes to him he has disquieting dreams and awakes as unrefreshed as if he had been "out on a spree" the night before. He begins to feel he will never get well, that he is going into a decline, that he will become insane, or that he is getting "paresis" or that some other dreadful termination to his illness is bound to oc-

cur, and he often thinks of suicide as the only means of relief. In addition to these physical phenomena he may have hot flashes, with alternate flushings and palings of the face, or creepy chills along the spine and legs. He may have frontal or occipital headaches, usually during the day only, or a feeling of weight on the top of the head, or of constriction about the temples, or a burning spot on the vertex, or a general tenderness of the scalp and weakness or pains in the back of the neck. Sometimes he has dizziness, spots come before the eyes, and there are buzzing or ringing sounds in the head. He may have cold hands and feet and wandering pains in the back, chest or abdomen, or periods of numbness of the limbs. Sometimes pain in the lumbar region is a constant symptom. The special senses are not seriously affected, though in many cases the eyes soon tire from use, the eyeballs ache and the vision becomes blurred. The sense of hearing may be painfully acute. All the reflexes are as a rule exaggerated, though in extreme cases the nerve exhaustion may be so great that they are diminished. Acceleration of the pulse-rate from slight causes is a constant symptom. Pressure on some tender point of the body will raise the count ten to twenty beats where it will remain for one or two minutes (Rumpf's symptom). The respirations are normal in rate, but there is sometimes deficient expansion. The temperature is normal. The composition of the blood is often normal, though there may be more or less anemia. The heart's action is often feeble, encouraging the local congestion. The skin is active, perspiration being profuse and easily induced, and sweating of the palmar surface of the hands and fingers is sometimes a persistent and annoying feature.

The digestive function is often more or less affected, nausea, anorexia, flatulence or constipation, being common symptoms. Rarely there is a persistent mucous enteritis, together with a flabbiness of the belly-wall. There is often more or less relaxation of the ligaments of the stomach and colon with a consequent sagging of these organs, and an increased difficulty in evacuating their contents. There are probably few cases that do not show in the urine or feces some evidence of defective metabolism. In rare cases one finds a transitory albuminuria; a temporary glycosuria is more common, while excess of uric acid or calcium oxalate is the rule rather than the exception.

The sexual function is irritable and weak, and coitus is so unsatisfactory that after each indulgence in it all the symptoms are aggravated. Desire is more or less absent, and the pleasures of normal intercourse are diminished. Even in case the desire is unabated the first orgasm is usually premature, and there is prolonged wait for the second erection, while excessive indulgence may be followed by involuntary emissions. There is sometimes a tingling in, or a numbness of, the penis, or a feeling of wetness and coldness of the genitals. At times there is pain in one or both testicles, or in the scrotum, groin or urethra. Itching of the skin of the scrotum is sometimes a prominent and distressing symptom, especially at night.

In cases in which the sexual symptoms are prominent there may be, in addition to the other physical phenomena enumerated in the beginning, a haunting dread of approaching impotence, or the feeling that the self-abuse or unnatural practices that have been indulged in at some former time are the cause of all the trouble and that the damage can never be repaired. Some feel that their appearance or movements betray their condition and are in consequence thrown into a flutter by a scrutinizing glance and avoid meeting people as much as possible. Rarely, in cases of neurasthenia there is an actual pyschical impotence; more commonly there is a peculiarly capricious sexual preference in regard to person, condition or surroundings. Of course the entire catalogue of symptoms that have been enumerated does not fall to the lot of any one patient; in extreme cases he may have most of them, and even others in addition, while in the mildest he may complain only of lack of vigor, mental or physical or both, with a tendency to hypochondriasis. The bulk of the cases fall between these extremes.

In the current loose classification the term "sexual neurasthenia" has been applied to those cases only that manifest predominant sexual symptoms, while other cases have been called cerebral, gastric or spinal neurasthenia, according as the symptoms seemed to point more or less definitely to an abnormal condition of one of these great centers of reflex activity. The overlapping of the symptoms of these different varieties has added to the confusion of the whole matter and rendered the treatment of neurasthenia uncertain and therefore difficult. Manifestly the final proof of the correctness of a diagnosis is the therapeutic test. Whenever the removal of an actual morbid condition results in the cure of the neurasthenia it is but fair to assume that this lesion was the primary cause of the neurasthenic symptoms. The recognition of the important rôle played by lesions of the genital tract in the production of all sorts of morbid conditions in women has done more than anything else to raise gynecology to the dignity of a specialty. Is it not absurd, then, to allow a faulty classification of neurasthenia to mask the importance of such lesions in the male in the causation of seemingly remote and disproportionate systemic disturbances? By ceasing to limit the application of the term sexual neurasthenia to those cases which show prominent sexual symptoms, and extending it to include all those cases of neurasthenia in which lesions of the genital tract are found to be the source of the trouble, we shall not only be putting the use of the term upon a rational foundation, but we shall tend to secure a proper recognition of the far-reaching systemic effects of genital lesions in the male; and emphasize the necessity of a thorough examination of the genital tract in all cases of neurasthenia.

Treatment.—In the treatment of sexual neuras-

thenia two indications are to be met, namely, the removal of the genital lesion and the eradication of the secondary effects. In mild cases the cure of the genital lesion and the consequent removal of the original source of irritation will suffice for the cure of the neurasthenia, for the patients are in fairly good physical condition. In those of more pronounced types, however, the neurasthenic habit has become more firmly grafted upon the system and measures must be taken to attack the condition directly, either after the removal of the genital lesion, or, better still, while the course of treatment for the lesion itself is being carried out. These measures are in a word those calculated to build up the genital system, and re-establish a healthy mental and moral tone, and the choice of the particular means will depend upon the condition of the patient, his circumstances and environment. In rare cases complete change of surroundings and mode of life is imperative, but certain simple hygienic measures are easily carried out and are within the reach of patients in every walk of life.

Local Treatment.—We should never lose sight of the fact that true sexual neurasthenia is a disease of local causation, however effectively its secondary symptoms by their remoteness or severity may serve to mask the origin of the disease. Measures directed to the cure of the local trouble are, therefore, of prime importance and demand the earliest attention of the practitioner. The source of irritation may be congenital or acquired, and may be situated in any of the external or internal genitals, or at any point along the genital tract from the testis to the meatus. A long, tight prepuce, a partial or complete phimosis, a small meatus or a congenital stricture behind it, a hypospadias or epispadias, or an undescended testicle are among the congenital causes of sexual neurasthenia, while among the acquired causes are chronic urethritis, chronic prostatitis, chronic seminal vesiculitis and chronic epididymitis, to which may be added varicocele, tumors of the prostate, and of the testicle, traumatism of the external genitals and defective innervation due to traumatism, disease or exhaustion of the sexual center in the spinal cord. To these may be added indirect or contributing causes, briefly those productive of pelvic, and especially prostatic, congestion, such as sedentary life, constipation, hemorrhoids, ulcer of the rectum, fissure of the anus, prolonged bicycle riding, masturbation, onanism, and, above all, *coitus reservatus vel interruptus.*

These contributing causes must cease to act if we are to produce distinct and permanent benefit by our local treatment. The congenital causes are usually amenable to operative treatment, and since, with the exception of small meatus, congenital stricture, and redundant prepuce, they do not figure in the cases cited above, we need not take time to consider them at length. It is the acquired causes, therefore, that will receive our attention in the space that remains at our disposal and, first of all, chronic urethritis as being one of the causes that has received least consideration at the hands of previous writers upon this subject.

This condition is characterized by lesions of the urethra, usually contributing tell-tale elements to the urine in the form of shreds, flocculi and coarse or fine flakes, most abundant in the first of the three classes, and usually entirely absent from the third. Microscopic examination of a centrifuged sample shows these flakes, shreds and flocculi, to be composed of pus, epithelium and bacteria, and representing the exudate that has formed upon areas of the urethra which are undergoing a more or less active inflammation. These areas may be situated anywhere along the urethra, but commonly anterior to the membranous portion. The bulb and the inch just in front of it are their favorite sites, and by the aid of the urethroscope they are seen to surround one or more gaping follicles, indicating that although the greater part of the urethra entirely recovered from the original urethritis, the inflammation has persisted in the depths of a few follicles, an ichorous discharge from which upon the adjacent surface of the urethra, together with the local congestion, combine to make it impossible for healthy epithelium to form at that point. There is another sort of hyperemic patch that contributes shreds to the urine, usually of considerable size, which is only secondarily due to a former urethritis. It lies directly behind a stricture, and is the result of the retention of a little urine behind the stricture after each evacuation of the bladder. The bacteria always present in the urine in considerable numbers are here allowed to mutiply and decompose the urine without the hindrance in the way of constant accessions of fresh acid urine which prevents the same results taking place in the bladder. The irritation produced by this broken-down urine is sufficient to keep up an inflammation over the area upon which it rests, an inflammation which will never heal as long as the stricture remains to dam back a little urine after each act of micturition. Inasmuch as the inflammation is due to chemical irritation instead of specific organisms, it does not extend so deeply into the tissues, and in these patches therefore we see no gaping glands.

So far we have spoken only of those patches that contribute elements to the urine. There is another sort of patch seen by the aid of the urethroscope, which is altogether different in appearance, being yellowish-white in color and usually having a granular look. This has its origin in exactly the same way as stricture and represents an area the epithelium of which has been entirely denuded during the acute attack, the submucous layer infiltrated, and upon its surface an exudation of plastic lymph poured out which has subsequently become organized in the form of granulation tissue. These granulation areas, which are in reality a variety of indolent ulcer, receive slow but constant accretions until not only is the thickness of the lost layer of epithelium replaced, but a distinct elevation appears upon the surface

of the urethra, producing a narrowing of the canal depending in a degree upon the rapidity of accretion and the length of time over which the process has extended. A narrowing of the canal produced in this way is much more difficult to cure than an annular stricture, since the soft tissues on the opposite wall of the canal do not offer a sufficient amount of counterpressure upon sounds and dilators. In the case of an annular stricture, on the contrary, the entire ring of granulation tissue is capable of exciting counterpressure upon the dilating instruments, thus presenting the paradox of a morbid condition contributing to its own cure. As a rule, the strictures found in cases of sexual neurasthenia are large ones, for the reason that small strictures give rise to urinary symptoms so severe as to mask the more remote genital trouble and the reflex disturbances resulting therefrom.

These large strictures should be stretched by means of sounds, or better still by the Oberländer or Kohlmann dilator, as they rarely cause traumatism by their introduction and the distention is uniform and gradual. After each dilatation the urethra should be irrigated by the Janet method, using a solution of nitrate of silver beginning at 1 to 16,000 and increasing the strength up to the point of tolerance; the treatment should be given twice a week, sometimes every other day. In the case of a particularly dense stricture that will not yield to the treatment by gradual dilatation, it must be cut by the Otis urethrotome if over 15 F.; if smaller, by the Maisonneuve. A deep stricture of this sort requires the perineal operation on a urethral guide. Post-operative dilatation should be made, followed each time by silver nitrate irrigation of the urethra and bladder. If after the normal caliber of the urethra has been restored inflammatory areas still remain, the treatment is the same as that to be followed in cases in which no stricture is present. This consists in stretching the urethra a degree or two at each session by means of the urethral dilator in order to squeeze out the inflammatory accumulation of the infected follicles, and irrigations of the canal immediately afterward by the Janet method with silver nitrate solution in strength graduated from 1 to 16,000 to 1 in 2,500. In certain stubborn cases topical applications of silver nitrate solution through the endoscope may be found useful, beginning with a grain to the ounce and increasing its strength as high as ten grains. If the meatus is small it should be cut, as a narrow meatus is really a stricture, and not only interferes with the flow of urine, causing congestion of the bladder and prostatic urethra by back pressure, but renders examination and instrumentation of the urethra impossible.

Congenital stricture located in any part of the glans, from the meatus to the beginning of the fossa navicularis, should be treated in the same way by inserting a bistoury into the urethra to a point behind the stricture, and cutting outward and downward toward the frenum, ending the incision externally at a point that will increase the size of the meatus to about 35 F. The subsequent contraction will reduce this to 30-32, which is large enough for all purposes of instrumentation.

Chronic posterior urethritis should be treated locally by means of the deep urethral syringe or by irrigations, the latter being by far the best, as they do not necessitate the irritation and possible traumatism attendant upon the introduction of the instruments into the inflamed posterior canal. By the Janet method of intravesical irrigations, the urethra is ballooned out and the solution brought into contact with the mouths of the follicles of the glands in every part of the inflamed area. Permanganate of potash and nitrate of silver are the best to use in this way. For daily irrigations permanganate is better, used in the strength of 1 to 10,000 to 1 to 13,000, but for less frequent use silver nitrate is to be preferred. Throughout the treatment it is usually well to administer internally an antispasmodic such as codeine, belladonna or hyoscyamus, if there is much irritation, and diluents in the form of one of the alkaline salts or potash or lithia.

The treatment of inflammation of that part of the prostate gland immediately surrounding the urethra may follow the same lines, but deeper involvement of this organ, as well as inflammation of the seminal vesicles, must be treated through the rectum. For this purpose irrigations by means of the rectogenital tube with a normal saline solution at the highest temperature that can be borne is of the utmost value. The irrigations should be made every night before retiring. In addition to these, massage of the prostate should be given every five to seven days.

While receiving massage by the rectum the patient stands with his feet wide apart, his body bent at an angle of 75 degrees, and his hands resting upon some support, as a table, or chair. The surgeon introduces his forefinger into the rectum and massages with a firm even pressure, and slight rotary movement of the finger-tip, beginning at the basis of the vesicles and gradually moving down to the apex of the prostate. A thin finger-cot will keep the finger clean and still allow the surgeon to thoroughly manipulate the parts. It is well to give the urethral irrigation of silver nitrate by the Janet method after each massage.

In place of the simple saline irrigation a hydroelectric douche may be used, an electrode being fitted into the rectogenital tube and connected with the positive pole of the galvanic battery. This has a sedative influence upon the inflamed tissues and is extremely grateful to the patient. After the inflammation and tenderness have left the parts the electrode may be connected with the negative pole of the galvanic battery, or with either pole of the faradic with the purpose of stimulating to absorption.

When varicocele is present the circulation in the cord is impaired and there is increased pressure upon the testis, epididymis and vas. This can be relieved by the open operation, the dilated

pampiniform plexus being excised and the cut ends remaining brought together and sewed. The beneficial result is not immediate, since there is a temporary thickening at the point of union of the severed ends, and not until this mass has been absorbed will the circulation in the cord be completely restored and the mechanical pressure entirely removed.

General Treatment.—Under this heading we must consider the diet, the digestion, regulation of the bowels, exercise and hydrotherapy, the cold sponge-bath being of primary importance. The sedative effect on the general nervous system of the cool sponge-bath is only equalled by the stimulation of the internal secretion, due to a temporary determination of an increased quantity of blood to the interior of the body. Unnecessary as it may appear at first glance, it is of some importance to give the patient minute directions as to the method of taking his sponge-bath.

Patients with an enfeebled circulation, and not accustomed to it, will shrink from the experience at first, for it must be remembered that many people are not accustomed to bathing; in fact the majority of people in the country towns, even the well-to-do, have no bathrooms in their houses. This applies especially to old towns, as in new settlements houses are built with all the modern improvements. Many people living in cities always take warm baths by preference—in fact, I know an athletic trainer in one of the largest athletic institutions in the world, who told me that he cannot take cold baths, and never does. It is well in such cases to direct the patient to stand in a few inches depth of warm water while sponging the body with cool water, and to carry out the process methodically for the first few times in the same order each time, the limbs being sponged first. Beginning, for example, with the left arm, taking next in regular order the right arm, left leg, right leg, neck, chest, abdomen and lower part of back, concluding by squeezing a spongeful held at the back of the neck so that the water will flow down the spine. Before the sponging of each segment of the body, the sponge should be dipped in cool water, and partly wrung out. Rapidity of movement is of prime importance. The entire sponging process should not take over two minutes and the vigorous rub-down following three minutes more. The patient should then dress as quickly as possible, and the eating of a light breakfast should not be delayed more than fifteen or twenty minutes. The brisk exercise has awakened an appetite, and the transient internal congestion has started a flow of gastric juice, which will be felt in these neurasthenics, who often have hyperchlorhydria, as a dull burning in the pit of the stomach if the breakfast is longer delayed.

The dull feeling in the head of which neurasthenics complain, the feeling of having been on a spree the night before, which is usually the result of a passive cerebral congestion, often vanishes under the vasomotor stimulation of the sponge-bath in a manner almost magical, and this is one of the strongest factors in winning over the patient to a faithful carrying out of a procedure from which he at first instinctively recoils. In selected cases of sufficient vigor, sea-bathing, cold douching, the shower-bath, and the plunge may be advised, though in nearly every case the indications are best met by the cold sponge-bath.

Massage, in the hands of an expert and conscientious manipulator, is also good, as by this means the muscles and internal organs receive the same stimulation that would be derived from active exercise, while the central nervous system, having no demand for the expenditure of energy made upon it, receives the benefit of the improved circulation as clear gain. It is almost incredible to what a degree the tone of the body can be reduced in these cases of sexual neurasthenia, in which the symptoms are considered by some simply imaginary.

The diet in every case should be generous, and largely nitrogenous, the sugars and starches being greatly restricted. Rare beef and mutton, with plenty of the green vegetables, oysters, raw or lightly cooked, baked and boiled fish, eggs, milk, curds, koumyss, and fresh butter used in generous quantities, should form the foundation of the regimen. Highly seasoned dishes and sauces, pastry and rich desserts, pickles, pickled meats, or fish, and everything cooked by frying should be religiously shunned. Coffee, tea, and alcohol should be avoided, but water should be drunk freely. Most neurasthenics drink too little water, and it is well to prescribe a certain amount to be taken every day, say one and one-half to two quarts. Habitual tobacco smokers should be instructed to cut down their allowance to one-half, but, preferably, should limit themselves to one after-dinner smoke. There is nothing in the calendar so bad for neurasthenics as cigarette-smoking, especially if the smoke is inhaled.

Another, and by no means less important matter to attend to, is the regulation of the bowels. The cold bath in the morning already spoken of stimulates the secretions and the increased peristalsis which also results will of itself, as a rule, insure a movement. This, in conjunction with the establishment of a regular habit of visiting the toilet immediately before or after breakfast, has frequently served to completely overcome the sluggish, constipated habit so prevalent in this class of neurasthenics. In cases in which these measures are not sufficient of themselves to initiate regularity of the bowels the administration for a short time of fluid extract of cascara, twenty minims night and morning, or, better, fifteen minims, t. i. d., will overcome the inertia and pave the way for the establishment of a periodic evacuation.

The patient's leisure hours should not be allowed to drag for want of quiet, wholesome amusement, and he should be as much in the open air as possible. Exciting and exhausting amusements, of course, prove injurious to those who are already bankrupt in nerve force. An

amount of exercise in the open air carefully regulated so as to fall within the limits of fatigue is another hygienic measure of the greatest importance. For those who have not much leisure, walking from their place of business to their homes is an excellent way of taking open-air exercise. Where the distances are great and fatigue easily brought on, it is well to walk but part of the distance and increase it gradually. By increasing the walking distance a block a day the patient will soon be able to cover quite a distance without much difficulty. More benefit will be derived from walking a few blocks briskly with head erect, shoulders thrown back, and arms swinging freely, than by languidly strolling along any number of blocks. Nothing fatigues so quickly as lolling along in the lackadaisical manner to which the neurasthenic is prone.

For the neurasthenic golf is one of the best forms of exercise, sailing and fishing are also splendid pastimes. Where surroundings are favorable he could not do better than to acquire a mild form of golf-mania. Golf is the valetudinarian's game *par excellence*. A moderate amount of horseback-riding with the use of an appropriate saddle (one for example of the McClellan type used by our cavalry, which obviates the pressure upon the perineum) is a form of exercise that cannot be too highly commended for almost every case of neurasthenia.

For the insomnia of which these patients complain, nothing does so much good as the establishment of regular hours of retiring and rising, the eating of a light supper followed by a few minutes of calisthenic exercise before going to bed. The calisthenics draw blood away from the brain and the light meal eaten before retiring, besides calling a certain amount of blood to the viscera for the process of digestion and thus still further reducing the cerebral hyperemia, supplies an amount of energy in excess of that required for the merely vegetative functions that go on during sleep, and hence affords a distinct addition to the vital resources of the body.

By such simple hygienic rules as those here laid down I have known a man whose weight had remained stationary for five years, but which was twenty-five pounds or more below the normal for his frame, to gain these twenty-five pounds in good, hard flesh within a period of three months.

In some of these cases the patients are so nervous that business has to be abandoned for the time, in which case a change of air and scene is of the greatest benefit. Probably nothing in this line equals a sea voyage for those who are not persistent sufferers from sea-sickness.

In the way of office treatment for the general nerve exhaustion static electricity has a decided value. The manner of its application, however, must receive careful consideration. A weak, nervous, irritable patient will be apt, at first, to regard such a thing as a dreadful ordeal, and steps must be taken to relieve him of his trepidation if we would not have this counteract the beneficial effects of the treatment. For this reason he should be given a chance to get acquainted with the machine before any sudden attempt is made to treat him.

The insulation should be either positive or negative, according to the physical make-up of the patient. The cool breeze from the point electrode produced by grounding the negative pole is adapted to muscular and full-blooded cases, while the warm breeze resulting from grounding the positive pole is the one to be used for the feeble and anemic. The treatment should be given every other day, and the duration of each should be about ten minutes of the electric bath and five minutes of the breeze. The more vigorous local treatment with sparks is desirable only in cases in which some persistently tender point of the body does not yield to the milder measures. The improvement in the patient's condition is often apparent from the start, weak and anemic patients taking on color and weight, and the full-blooded ones showing the sedative effect of the positive electrization in the diminished irritability of the nerve centers, manifested by greater equanimity, diminution of the exaggerated reflexes and the ability to obtain sound and refreshing sleep.

75 West Fifty-fifth Street.

MASTURBATIONAL NEUROSES.

BY WILLIAM C. KRAUSS, M.D.,
BUFFALO, N. Y.

OF late there has been a growing tendency to disregard the effects that masturbation exerts upon the nervous system of individuals in general, without sufficient regard for those who can ill afford such exertions or such excesses. To be sure, all youths do not possess that power of inhibition which permits of a healthy, liberal exercise of this function, and these unfortunates are the living examples which prompt denunciations and protests upon the perniciousness of the habit as a whole.

In one of the latest works on sexual debility by a distinguished and well-known physician, in the chapter on masturbation he has combated the old and time-honored belief that indulgence in this habit is the necessary prelude to both physical and mental degeneration, and, while not glossing over the dangers which may, under certain conditions, result from the habit, he has attempted to point out the folly of the hysterical denunciations which have been heaped upon it by pseudo-philanthropists and ignorant medical men.

In a paper read before one of the county societies of Western New York a short time ago, an intelligent and experienced practitioner defended the habit and championed the cause of those engaged in it.

The upper crust of society and some of our ultra-medical men contend that it is a perfectly innocent and legitimate form of exercise for the amusement and gratification of mankind, rich or poor, young or old, male or female. They claim

for it no statute of limitation, being alike harmless to the nerve-bankrupt as well as to the nerve-plutocrat, to the hereditarily strong as well as to the hereditarily weak. For my part this pastime has but two redeeming features: First, in this age of commercialism it is cheap and within the reach of all; second, from a purely selfish point of view, it helps to fill the coffers of the otherwise needy and struggling physician.

We are entering upon an age of nerve tension and consequently nerve suspension, nerve wear and tear. The acme of physical and mental activity has fallen from the decade extending from the fortieth to the fiftieth year to that extending from the thirtieth to the fortieth. Indeed, one of the great English experts sent to this country to study the secret of America's unparalleled leap into the commercial world found none other than young men at the head of all large industrial enterprises. Thus at an early age an unusual amount of brain activity is demanded from the growing youth.

To prolong the period of boy-life is to prolong the period of *growth*. This is a simple physiological law, and a very obvious one, and, whatever other things may be said in favor of purity, it remains, perhaps, the most weighty. To introduce sensual and sexual habits—and one of the worst of them is self-abuse—at an early age is to arrest growth, both physical and mental. And what is even more it means to arrest the capacity for affection.[1]

It is the duty of the medical men, the priests of the body, and the teachers of the truths of medico-psychology and physiology, to help and teach them by our counsel and our knowledge. We are about the only persons who can help a youth strike a happy medium between blissful but dangerous ignorance and prurient suggestive knowledge. It must *not* for a moment be inferred that every lad once addicted to this habit is a confirmed neurotic, for boys healthily constituted in body, mind, and morals do not tend to come under its influence to any very hurtful extent. But the habit of masturbation in certain other cases acquires a power that is dominating and destructive to body and mind. The causes of this are either an innate morbid strength of the reproductive instinct or much more frequently an innate weakness of the controlling faculties, or a lack of inherent brain stability, or an incapacity of organic repugnance to what is unnatural. Such weaknesses are apt to occur in the children of neurotic families. In such cases the habit becomes deep-rooted, and nothing short of exhaustion will satisfy their depraved appetite. The weaker and more nervous he becomes the more he indulges, till the point of absolute breakdown of body and mind is reached. It seems to get possession of him like an evil spirit, and to dull and paralyze all his better feelings and his natural instincts. The heredity and temperament are no doubt the true explanation of the opposing statements that are confidently made, on the one hand, that this habit seldom does much permanent harm, and, on the other, that it is the root of most of the evils of boyhood, and that it ruins the health of every one who has ever indulged very much in it. Like all other habits, it is the one who least can afford it physically and mentally that falls the easy victim.

The special point that I wish to make is that in these cases nerve disease of whatever form acquires a vise-like grasp that taxes the skill and art of the physician to the utmost before yielding.

Within the past few years I have been surprised at the number of such cases coming into the consultation room, often admitting, occasionally denying, the habit. From my experience it seems to have an opposite effect upon the two sexes—dulling the mental and making clumsy the physical exertions of the male—while in the female it quickens and excites the physical and psychical movements. The male is rendered hypoesthetic, the female hyperesthetic. The neurosis resulting from this habit is neurasthenia, the psychosis, hebephrenia.

Since Beard first described neurasthenia many diverse opinions have been expressed concerning the relationship of sexual irregularities to neurasthenia. Gilles de la Tourette, in his little monograph on neurasthenia, following the traditions of Charcot's school, dismisses the question of any sexual causation without discussion. Binswanger,[2] while admiting that nearly all neurasthenic persons acknowledged masturbation at some period, considered it not an important cause of neurasthenia, only differing from coitus by the fact that the opportunities for it are more frequent, and that the sexual disturbances of neurasthenia are, in the majority of cases, secondary. Rohleder, on the other hand, who takes a very grave view of the importance of masturbation, considers that its most serious results are a question of neurasthenia. Krafft-Ebing has declared his opinion that masturbation is a cause of neurasthenia. T. D. Savill[3] regards masturbation as an important causal agent of neurasthenia. Collins and Phillip,[4] in an analysis of 333 cases of neurasthenia, found that 123 cases were apparently due to overwork or masturbation.

Freund concludes that neurasthenia proper can nearly always be traced to excessive masturbation or to some interference with the normal sexual act. This view is confirmed by Gattel's careful study.[5] Gattel investigated 100 consecutive cases of severe functional nervous disorder in the clinic of Prof. Krafft-Ebing at Vienna and found that in every case of neurasthenia in a male (28 in all) there was masturbation, while of the 15 women with neurasthenia only 1 is recorded as not masturbating, and she practised *coitus reservatus*. Irrespective of the particular form of

[5] Ueber die Sexuellen Ursachen der Neurasthenia und Augstuenrose, 1898.

the nervous disorder, Gattel found that 18 women out of 42 and 36 men out of 58 acknowledged masturbation.

Taking at random twelve private cases of this habit seen by me within a short time I found four cases of insanity and eight of neurasthenia. Two of the four cases of hebephrenia partially recovered, and the other two, who were persistent masturbators, have shown no improvement and are rapidly sinking into dementia. Of these four cases three occurred in one family, being brothers, with neurotic, high-strung nervous parents. In the two cases partly recovered treatment was long continued and at times discouraging.

Perhaps the most interesting case occurred in a young woman who was a neurasthenic and also afflicted with a general neuritis. Long-continued treatment helped to control the neurasthenic symptoms, but the neuritic pains would not yield to any form of treatment. Another case, occurring in a young lady, was treated carefully for a long period without any satisfactory results. The youngest patient was a precocious lad, aged six years, who showed marked proficiency in this habit, and was evidently a candidate for high neuropathic honors.

In closing, I wish to warn against giving a favorable prognosis in cases of functional nervous diseases with an underlying history of masturbation coupled with a neurotic family history. Cases giving no history of masturbation, which fail to respond to treatment after a sufficient interval, should be most rigidly interrogated, and in many cases the suspicion of masturbation will be verified. It is almost useless to try any form of treatment or to expect to obtain any definite results in the functional neuroses if this habit is not discovered and corrected. If, then, this habit is so widespread among the young; if it tends in suitable cases to undermine the physical and psychical forces; if it renders its devotees almost impregnable to rational scientific treatment, is it not a practice which should be discouraged rather than encouraged, defeated rather than surfeited? My own opinion may differ from others, but from my experience I would rather treat any other form of nervous disease than a case of masturbational neurosis.

MEDICAL PROGRESS.

Fractures of the Leg.—HUSCHENBETT (*Centralbl. f. Chir.*, 1901, No. 24) describes what experience has taught him is a most serviceable splint for the treatment of fractures of the upper and lower parts of the shin. It is based on the theory that the ambulatory treatment is more and more becoming the method of choice among surgeons, especially in the aged among whom mere confinement to bed is disastrous. The details of the splint are that after reduction of the deformity and careful apposition of the fragments a carefully applied plaster dressing is applied from the toe-bases to the upper third of the thigh. After this is dried ordinary heavy-weight hoop-iron is taken and made into a stirrup, with the vertical pieces extending all the way up each side of the lower extremity to the upper edge of the plaster bandage. The iron is cut and an inner and outer hinge is made in it opposite the knee. After bending the iron to make it conform carefully to the leg a water-glass bandage is carefully laid over it and the whole hardened. The knee is then exposed until the patient can produce flexion and extension and the ankle is freed by cutting away all that covers the foot. In this splint the patient walks on the bottom of the stirrup and the thigh receives the weight transmitted to it through iron braces.

Hydrocele.—OHL (*Deutsch. Zeitschr. f. Chir.*, B. 59, 45 and 6, 1901), reports the immediate and remote results in nineteen cases of simple hydrocele operated on by the method suggested by Winkelmann in 1898. Briefly, this consists in opening the sac, evacuating the contents and then wrapping the tunica carefully about the testis and replacing it within the scrotum. The skin is then closed by some of the well-known procedures. Among the series here reported many were followed up by the operator himself and the others by the family physicians. In all it was found that the testicle was mobile, insensitive and in every way normal. The scar-tissue about it was of very moderate extent and did not interfere with any of its features. In many of the cases it took a most careful examination to show how the normal and operated sides differed. The ease and rapidity with which the operation may be done and these very flattering results seem to make the operation the one of choice.

Tonometric Examinations in Cardiac Cases.—Complicated apparatus necessitating special experience is of very little benefit in assisting the ordinary physician to follow the results of treatment, and it would seldom be possible for one to use Gaertner's tonometer which is employed so advantageously by T. SCHOTT (*Med. Rec.*, June 29, 1901) in his Nauheim treatment. By this instrument the differences in blood-pressure in the smaller arteries are easily determined. He has made a large number of experiments with this apparatus and finds that the results are reliable and constant. The action of the Nauheim bath is especially noted, and he finds that after the patient has been in the bath from two to five minutes both the pulse and respiration decrease, but that the blood-pressure constantly rises for a period of from eight to ten minutes. A very decided change is usually seen, unless the condition of the heart is such that the bath treatment is contra-indicated. In several cases where compensation could not be hoped for or in severe cases of myocarditis, the blood-pressure was much diminished and the general condition of the patient impaired.

Mortality after Gall-Stone Operation.—H. KEHR (*Münch. med. Woch.*, June 4, 1901), the well-known specialist, reviews 100 operations for

gall-stones done by him during the last year and concludes that the mortality at the present day is very low if the operation is performed before pathological changes have set in to an advanced degree, but that it is high if such conditions as carcinoma and purulent cholangitis are encountered. Of the 16 patients that were lost, 4 died of cholemic hemorrhages, in 5 the stomach or intestines were involved in the operative procedure and 4 cases were complicated by purulent inflammation and cancer. Only one died as a result of operation, an extremely emaciated woman, sixty-two years of age, who developed pneumonia five days after a cystectomy and drainage of hepatic duct. The mortality was considerably higher among males than females which may be due to many causes; thus, cancer of the pancreas is more frequent in men, they often stand narcosis and manipulation of the peritoneal cavity less well than women and their general condition often is less satisfactory. Pneumonias generally are right-sided and are often embolic or a result of direct infection by way of the lymphatic channels. In conclusion, the author draws a comparison between the medical and surgical treatment of cholelithiasis; the former cures 40 per cent. of cases; the latter, 95-98 per cent.

Typhoid Spondylitis.—A case of typhoid spine is related in detail by A. KUHN (*Münch. med. Woch.*, June 4, 1901). The patient was convalescing from a severe typhoid which had been complicated by thrombosis of the right femoral vein, when, on the eighty-third day of his disease, after having been free from fever for thirty days, pain developed in the left lumbar region. This disappeared after Priessnitz packs, but returned after six days when the patient was allowed to get up for the first time. The spleen was slightly enlarged and friction sounds could be heard over it. Soon the spinous processes of the lumbar vertebræ and the sacrum became tender to percussion and after a little over a month a distinct kyphosis developed in the region, with fever and exaggerated patellar reflexes, but no sensory, bladder, nor rectal disturbances. Convalescence was satisfactory and after six weeks the kyphosis had almost entirely disappeared. The diagnostically important symptoms which this case presented were the vague lumbar pains and tenderness, later more strictly limited to the spine, the distinct swelling over the area and lastly the kyphosis. The kyphosis has a certain resemblance to that of tuberculous spondylitis and one must in these cases always rule out an exacerbation of an old tuberculous process revived by the typhoid fever by the previous history, general condition and examination of the lung. Spinal symptoms, indicating involvement of the cord and of such character as incontinence and retention of urine, disappearance of patellar reflexes, paresis, spasms of the adductors, may occur but often, as in the cited case, are absent.

Tapping in Pleural Effusion.—In an editorial the *Therapeutic Gazette* (June 15, 1901) gives a few remarks upon the rational treatment of pleural effusions. Many of the older physicians still believe in the administration of concentrated saline purges or hydragogue cathartics from the vegetable kingdom, unmindful of the fact that this procedure often fails to remedy the condition owing to the plastic exudate with which the pleura is covered which prevents all absorption. Attention is called to a mistake often made in the drawing off of fluid, namely, the too great hurry with which this small operation is done. Thus, neighboring parts are suddenly rather than gradually relieved of pressure and secondary changes are liable to follow in that the lung may tear itself free from adhesions or circulatory disturbance may occur. In case of pus, free drainage is, of course, indicated, but it may be well to relieve pressure several hours before the operation by preliminary puncture.

Patellar Suture.—BARKER (*Archiv f. klin. Chir.*, B. 63, H. 4) states that in twenty-one cases he has sutured the fragments of the broken patella together in the following manner under both local and general anesthesia. The lower fragment is held by the thumb and forefinger and the joint opened by passing in a knife horizontally with the cutting edge upward toward the long axis of the patellar until that bone is encountered. Through this little hole the fluid and blood within the joint are pressed out. This emptying of the joint is important as decreasing the dangers of sepsis. A specially designed needle is then passed into this opening, behind both fragments and through the tendon to just beneath the skin above the upper piece. Its point is then cut down upon and a wire thread passed through its eye. It is then drawn out of the lower hole leaving the wire free in each incision. The needle is then passed in front of the fragments and receiving the upper end of the wire at the upper hole is withdrawn. The two fragments are now freed of clot and tissue by vigorous rubbing in the hands of an assistant and when opposed are fixed by twisting the wire up. It is then cut off and the stump hidden against the lower fragment. No joint reaction has occurred from its presence.

Pregnancy.—From a study of numerous cases, HERMANN KELLER (*Annales de Gynéc. et d'Obstet.*, May, 1901) finds that the period of accouchement corresponds to menstruation in the diminished activity of the nutritive processes. This period is characterized by a high percentage of nitrogenous matter in the urine, but by diminution in the volume of the urine, so that the total daily urea is low. This change is due to insufficiency of the liver functions, and is most marked in multiparæ. Once established, this hepatic insufficiency makes the woman more susceptible to renal difficulties, and to morbid influence, such as septicemia. The author thus finds new proofs in favor of Pinard's theory of the hepatotoxemia of pregnancy. Rest, milk diet, and the

drinking of water and diuretics facilitate the elimination of these toxic matters and tend to lessen their formation.

Nerve-Stretching in Chronic Ulcer.—Thirty cases of the chronic ulcer of the leg by nerve-stretching are reported by CHIPAULT (*La Méd. Moderne,* June 12, 1901). The technic includes (*a*) stretching of the musculo-cutaneous, internal saphenous, sciatic or external popliteal; (*b*) treatment of the ulcer itself, either by total ablation followed by suture, or curettement with disinfection when ablation and suture are impossible. Cure of the ulcer was effected in 26 cases, in some of which, however, there was a renewal of the trouble after a considerable interval.

Acute Colitis in Children.—It is a remarkable fact that the occurrence of acute colitis, or ileocolitis, in epidemic form is almost unknown, or at any rate unrecorded, in England, says EDMUND CANTLEY (*Lancet,* May 25, 1901). A small epidemic broke out in a London barracks, in rooms opening on to a common staircase. There were 13 families, consisting of 13 women and 30 children. Six children and 3 women were attacked and 4 of the children died. No origin could be found for the epidemic. In each case the onset was sudden, with vomiting, diarrhea and fever. At postmortem the whole large intestine was found to be inflamed and thickened, the inflammation extending up into the ileum. The author thinks irrigation to be of no service in the treatment of these cases, but supports the system and stops the diarrhea and vomiting by internal medication.

Neutral Red as a Stain for Nucleated Red Blood-Cells.—A very simple method for bringing out nucleated red cells is given by A. BETTMANN (*Münch. med. Woch.,* June 11, 1901). A small platelet of elder-pith is saturated with a concentrated aqueous solution of neutral red, a small drop of blood is then placed over it and the platelet then examined in the hanging drop. On viewing under the microscope, at first neither nuclei nor granules of the leucocytes is visible; the erythrocytes are stained a faint brownish-red and their nuclei are the only prominent structure visible, owing to their deep-brown color. The stain is admirably suited to study the changes which occur in the nucleus. This diminishes in size after a few minutes and often becomes star-shaped, and small granules separate and lie free in the protoplasm. After several hours the nuclei become decolorized, but they again become evident upon the addition of more neutral red. If the specimen is prevented from drying and if examination is completed within an hour, there is no danger of confusing the nuclei of the white cells with those of the red. The method is recommended especially for the rapid identification of nucleated erythrocytes.

Cystic Affections of the Breast.—The symptoms of cystic conditions of the breast are varied and many. The enlargement of the axillary glands in malignant disease is held to be more or less pathognomonic of such a condition, but in reality this is not the case, says A. M. SHIELD (*Brit. Med. Jour.,* May 18, 1901). There is scarcely any breast swelling, which exhibits any variation in size that is not cystic. Pain and local tenderness are found with the excessive secretion of fluid and disappear with its exit. Dimpling of the skin over a cyst is very often present, though this is supposed to be another sign of malignancy. In regard to treatment the author is conservative. Use the trocar and cannula in certain selected cases and, having made a diagnosis, the author advises that the tumor be dissected out, with free drainage in after-treatment in order that the blood serum may not be allowed to collect and become infected.

Urinary Calculi.—P. J. FREYER (*Brit. Med. Jour.,* May 25, 1901) gives the following as characteristic symptoms of stone in the bladder: (1) Increased frequency of micturition; (2) pain on micturition; (3) hematuria; (4) sudden stoppage of the flow of urine. The rectum should be examined to find out the condition of the prostate and seminal vesicles and to determine the presence or absence of organic deposits at the base of the bladder. The best method of making a diagnosis is by sounding. One should never use force in this procedure and thus set up traumatism. The author uses the Mercier solid steel sound, commencing with No. 6 English at the shaft and No. 10 at the bulb; in children, No. 2 shaft, No. 5 bulb. Small stones may often be made out with the aspirator and cannula, such as are used in the Bigelow operation. Suprapubic or perineal section may be necessary to make an absolute diagnosis. Pain in the loin and hematuria are the characteristic symptoms of renal calculus. Violent exercise, particular horseback-riding, will bring on a typical seizure. The presence of mucus and pus in the urine is an important symptom. Sometimes the stone can be located by means of the X-ray. Littré's electric cystoscope has in many cases been a most important means of locating calculi in the ureter, especially when they lie in the mouth of the urethral orifice. As a rule, the symptoms of urethral calculi are very obscure and the diagnosis is extremely difficult.

Roentgen-Rays in Warfare.—J. HALL-EDWARDS (*Lancet,* June 22, 1901) claims that his experiment with the Roentgen-rays at the base hospital in searching for bullets, whole or fragmented, and for pieces of shell, demonstrates the wisdom of carrying a very complete outfit as part of the medical equipment of each army hospital. The number of retained missiles is very small when compared with the number of all wounds made by them, simply because this includes a preponderating number of mere soft-part damage. In the number of penetrating bullet and shell wounds, however, whether perforating or not, a much larger percentage shows retained foreign bodies than had ever been supposed. His field of observation was not very large, because in the base hospital the patients have been filtered through from a number of field hospitals, where beyond question many good subjects for radio-

scopic investigation are lost. Out of 193 cases under him for X-ray diagnosis the surprising large number of 65 gave foreign bodies imbedded in the tissue. Of the total wounds 54, with 29 lodged masses, were in the thigh, hip, knee and leg (*i.e.*, between the ankle and the trunk); the hands had 19 total wounds with 8 retained projectiles; the upper extermity, 69 wounds with only 16 bullets found; the chest showed 7 missiles out of 18 wounds and the head 1 in 11 wounds. The most important element, however, was the unvarying precision of the diagnosis in every case.

Consumption and Excretion of Food During Training.—In a careful analysis of all food consumed and all products excreted by four members of the Harvard crew in 1900, M. O. ATWATER and F. G. BENEDICT (*Boston Med. and Surg. Jour.*, June 27, 1901) found that they ate about the same as members of other crews, and that their food had about 50 per cent. more protein and 16 per cent. more energy than that of men at ordinary occupations. They digested their food about as completely as most men, but one notable feature was the fact that the nitrogen excreted by the kidneys and intestines was much less than the total nitrogen of the food. The amount which was apparently stored in the body corresponded to an average of not far from 24 grams of protein per day, if no allowance is made for perspiration. Even after making such an allowance they were undoubtedly storing up considerable nitrogen, and it is questionable whether they are in good physical condition while doing this and also whether they receive the best diet suited for men training for such races.

Alcoholic Neuritis.—E. F. BUZZARD (*Lancet*, June 8, 1901) studied 120 cases of alcoholic neuritis in order to see to what degree alcohol was the sole etiologic factor in this disease. In opposition to most authorities he finds that "spirits," and not beer will more often produce the disease. Ninety-eight of the patients were females and 22 males. The males had an average age of 42.8 years; the females, 38.5 years. The writer thinks that in England alcoholic neuritis is more often found as a sequel to spirit-drinking than in other forms of alcoholism; also that clinical experience and evidence are antagonistic to the idea that arsenic is the cause of alcoholic neuritis. If good statistics were made in Scotland, where the disease is said to be rare, the average would be the same for spirits as in London.

Diacetic Acid in the Urine.—S. LIPLIAWSKY'S (*Deutsche med. Woch.*, No. 10, 1901) modification of Arnold's test eliminates some of the fallacies open to this and to Gerhardt's method. Two solutions are required, one containing 1 per cent. of paramidoacetophenon, made more soluble by the addition of 2 c.c. of concentrated hydrochloric acid, and a 1-per-cent. solution of potassium nitrite. Six c.c. of the first solution and 3 c.c. of the second are mixed with the same amount of urine; a drop of ammonia is added and the whole well shaken. Ten drops to 2 c.c. of this mixture, according to the amount of diacetic acid present, are then added to 10 to 15 c.c. of sulphuric acid, 3 c.c. of chloroform and 2 to 4 drops of ferric chloride. After one-half to one minute of careful agitation the presence of diacetic acid is shown by a violet tinge to the chloroform, while in the absence of this substance it becomes yellowish or reddish. The salicylates or other drugs do not affect the delicacy of the reaction which responds to 1-40,000 of diacetic acid.

Iodide of Potash in Asthma.—SIR W. T. GAIRDNER (*Lancet*, June 8, 1901) says that the use and knowledge of this drug in asthmatic affections are comparatively recent. Neither Cogswell (1837) nor Bouret (1855) made any mention of the employment of this drug in asthmatic affections, although both of them wrote excellent treatises on the therapeutic action of iodine and its compounds. In the late "fifties" Dr. Jephson of Leamington prescribed potassium iodide for the Rev. Dr. Barclay of Currie parish, who had suffered for many years with asthma and bronchitis. The prescription contained as many as fifteen ingredients and Dr. Barclay, to find out which one brought about the desired effect, tried each one separately until he discovered that it was the iodide of potash.

Uncinariosis.—This disease, due to a small thread worm (*Ankylostoma duodenales*), is very common in many of the tropical countries, but it is rarely found in natives of this country. T. A. CLAYTON (*Phil. Med. Jour.*, June 29, 1901) reports a case in a boy, nineteen years old, living in Virginia, who had presented signs of advancing pernicious anemia for several years. His mental development was also affected by the disease, but, strange to say, he had never had any intestinal symptoms. The hemoglobin was 30 per cent. and the red blood-cells 1,577,000. A search in the stools showed the presence of numerous ova of the worm and the administration of thymol caused the discharge of no less than forty-four of these worms.

Localized Vascular Disease.—Several obscure conditions, such as erythromelalgia and Raynaud's disease, have been looked upon as resulting from derangements of parts of the nervous system, probably the vasomotor or trophic centers. Some doubt has been thrown upon this idea recently by several investigators, especially B. SACHS and A. WIENER (*Phil. Med. Jour.*, June 29, 1901). A case of erythromelalgia was reported by them some time ago in which a foot was amputated on account of a large ulcer and a careful microscopical examination showed that nearly all the blood-vessels had become degenerated and sclerosed; they concluded that too much stress had previously been laid upon the nervous origin of these peculiar lesions. Since then they have followed three cases which presented symptoms of severe paroxysmal pains localized in parts of their extremities, sometimes symmetrical, usually confined to the toes or fingers, and finally followed by gangrene of a dry,

white character, necessitating amputation. In all these instances a marked phlebo- and arteriosclerosis was found together with a general neuritis, but it is believed that the vascular lesion was an important concomitant condition and there exists an intimate relation between the disease of the peripheral blood-vessels and many of the trophoneuroses.

THERAPEUTIC HINTS.

Boils.—Of undoubted value are remedies which improve the general condition, such as iron, arsenic, cod-liver oil, hypophosphites, and syrup of calcium lactophosphate. The urine should be examined as diabetes or Bright's disease may be the cause of the furuncle formation. In long-standing cases local irritations should be sought for, even old smoking jackets, sweaters, etc., being sources of infection. A boil may often be aborted by the application of iodine, boric acid, ichthyol, etc. Heitzmann's plaster for this purpose is:

℞ Ac. salicylici..... gm. 8.0 (℥ij)
Emplast. saponis ... 30.0 (℥ij)
Emplast. diachyli .. 15.0 (℥i)
Spread on cloth.

Another useful formula is:

℞ Tinct. iodi..... gm. 4.0 (℥i)
Ac. tannici ..... 2.0 (℥ss)
Pulv. acaciæ ..... 2.0 (℥ss)

Or a few drops of carbolic acid may be injected into the boil. The following ointment may be applied if pus has already formed.. It serves all the purposes of a plaster, allays pain, and does not favor reinfection. It is

℞ Iodoformi ..... gm. 4.0 (℥i)
Ung. vaselin. plumb. 30.0 (℥i)
Spread on lint.

Where boils are multiple, the intervening and surrounding skin should be smeared with equal parts of zinc oxide and vaseline with four per cent. of boric acid. After the boil has burst the cavity must be treated on ordinary surgical principles.—"Reference Handbook of the Medical Sciences."

Fractures of the Olecranon.—The forearm being held in extension, and the fragments adjusted, a compress of absorbent cotton or several thicknesses of soft woollen cloth is applied just above the apex of the process and held by strips of strong adhesive plaster laid on obliquely from above downward, and from below upward, so as to form a figure 8. These strips should not encircle the limb or compress the veins anterior to the joint. Now bandage the extremity from fingers to anterior fold of axilla with a flannel bandage, and then put on a plaster-of-Paris splint. If all goes well leave the splint on for two weeks and if there is still a little separation of the fragments remove and readjust the compress. The splint should be continued for six weeks, being reapplied about every ten days, the limb being bathed and massaged at each readjustment. After six weeks begin gentle passive motion and gradually increase motion and massage. When the tendon of the triceps holds the fragments in apposition a plaster splint is all that is necessary. In adjusting these splints see that the hand is held in supination, so that the olecranon is brought more truly in the axis of the olecranon fossa. It will probably be more comfortable and do no harm if the hand is put in semipronation after two weeks.—W. L. Estes in "The Treatment of Fractures."

La Grippe in Children.—Quinine is said to be deadly to the influenza bacillus, yet many writers oppose its use during any stage of the disease. Despres recommends sprays of chloroform-water, 5 to 1,000. Others advise spraying the nose with normal saline or boric-acid solution, then anointing with mentholated vaseline 1 to 10. Infants can safely nurse mothers with grip, but must not be fed from a spoon or cup used by the mother. The internal treatment consists of

℞ Liq. ammon. acetat. } aa. gm. 60.0 (℥ij)
Vin. mariani }

Sig. A teaspoonful in hot, sweetened water or lemonade every two hours.

For the later muscular aches and pains lactophenin and salol are effective. The pulmonary system may be stimulated with ammonium carbonate and nux vomica in small, frequently repeated doses. Bronchial adenitis requires some such remedy as iodide of iron arythmia and tachycardia require sulphate of sparteine, gm. 0.0075-0.015 (gr. ⅛-¼), and angina pectoris demands nitroglycerin or nitrate of amyl. If paroxysmal tachycardia is to be prevented, the digestion must be carefully looked after. Ear troubles must be treated early.—M. P. Hatfield in "The Acute Contagious Diseases of Childhood."

Foul Breath.—The teeth should be thoroughly cleansed, the gums sponged with myrrh and water, and one of the following allowed to dissolve in the mouth:

℞ Pulv. cinnamomi. } aa gm. 2.0 (℥ss)
Pulv. cardamomi }
Pulv. pimentæ.
Sacch. alb..... 4.0 (℥i)
Mucilag. acaciæ q.s.
Make fifty pills.

The digestive functions should be regulated, bad teeth attended to, and the mouth washed after meals with

℞ Thymoli ..... gm. 0.5 (gr. viij)
Sod. borat. ..... 1.0 (gr. xv)
Aqua, ad. .....c.c. 500.0 (Oj)

—E. E. Walker in "Reference Handbook of the Medical Sciences."

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, JULY 13, 1901.

FORMS OF DYSENTERY.

WE are entering upon the season of the year when sporadic cases and even more or less limited epidemics of dysentery occur in this country. The study of the disease by our army surgeons in the Philippines where dysentery is almost constantly endemic has thrown light on certain disputed points in the etiology and clinical forms of the disease that will be useful to the practitioner at home. The conclusions recently (April, 1901) published by the Chief-Surgeon's Office at Manila show the existence of three forms of dysentery, namely, mild catarrhal dysentery, scarcely more than a passing diarrhea and practically never fatal except in the very old or in patients extremely run down; specific dysentery due to the *bacillus dysenteriæ*, described by Flexner; and amebic dysentery caused by a special form of ameba, very probably a different organism from the common ameba of the intestine. Specific dysentery, the acute infectious form of the disease which produces so much havoc in camps, is probably not confined to the tropics though it is seen most frequently and in its severest form in hot countries. Prof. Osler has suggested that sporadic epidemics of this form of the disease apparently occur even in this country. Our dysenteric outbreaks in jails and camps exhibit at times all the clinical features of tropical dysentery. What the source of the specific microbe is under home conditions is difficult to say. Any observations that would tend to throw light on the method by which the micro-organism preserves its vitality between epidemics would be of great value for the prevention of the disease. The only absolutely sure method of differential diagnosis from other forms of dysentery in these cases is the agglutinative reaction of the blood serum of patients suffering from this form of dysentery upon liquid cultures of the bacillus dysenteriæ.

American observations in the Philippines appear to settle definitely the status of amebic dysentery. There would seem to be no room for reasonable doubt left that certain forms of amebæ are pathogenic for man and productive of dysentery as well as liver abscess. The question has been very much discussed of late years. The pathogenic amebæ are larger in size than amebæ found in the stools of patients ill with other diseases than dysentery or even at times in the passages of perfectly healthy individuals. In the *amœba dysenteriæ* red blood-corpuscles are frequently found enclosed. This phagocytic action as regards red blood-cells is never noted in the smaller non-pathogenic ameba, nor in the amebæ of straw when such are introduced into the system. Neither of these latter organisms produces any effect when injected into cats, while what is recognized as the true *amœba dysenteriæ* never fails to produce dysenteric disturbance in these animals.

The most interesting fact in the investigations in the Philippines is the hope of a curative serum for acute dysentery. This disease is usually very fatal in its ravages and has always been the main cause why armies at all times have lost more men by sickness than by bullets. The diagnostic value of the serum reaction seems to be beyond question. When this agglutinative power can be produced in animals their blood serum will, if injected intraperitoneally at the same time as bowel injections of virulent cultures are made, always protect the animal experimented upon. The work on the curative serum is, however, as yet in a purely tentative stage.

The best treatment according to the experience in the Philippines seems in acute cases to be the limitation of diet and the thorough cleansing of the bowel by large saline enemata. At the be-

ginning of dysentery, in sthenic cases, starvation for several days with a liberal allowance of water to replace that lost by the diarrhea seems to be indicated. The experience in children's summer diarrheas in recent years adds weight to these procedures as the most important therapeutic measures. Stimulants should be used, but only for absolute indications. Contrary to the usual practice the diet, when food is allowed in small quantities, should not consist of concentrated nitrogenous material, meat-juice and the like, but rather of diluted carbohydrates. The various cereal foods in thin broths are best. Somehow these do not seem to furnish the material for microbic growth that nitrogenous material does and, moreover, the acid fermentation to which these substances are especially liable makes the material present in the intestines an eminently unsuitable medium for the growth of bacterial parasites. With reference to amebic dysentery less is known, although here, too, limitation of the diet to the absolute needs of the individual and thorough cleansing of the bowels seem the most successful remedial measures.

THE RED CELLS AS BACTERICIDES.

The problem of the body's total unsusceptibility to non-pathogenic organisms and the destruction that often overtakes even infectious germs, when they have entered the circulation in not overwhelming numbers, seems to have met with a fairly adequate explanation by the theories of the bactericidal powers existing in the normal blood or making their appearance in response to the stimulation afforded by the presence of the invaders. These powers of self-defense have been almost universally attributed to bodies held in solution in the serum and emanating from the leucocytes, though the older idea that the white cells themselves by phagocytosis participated in the struggle has been overthrown by the researches of Buchner, Kolb and Schuster, who found that the bactericidal power of serum whose leucocytes had been destroyed by freezing was undiminished. In one case at least, however, that of the cholera vibrio, the origin of the specific anti-body is thought to be independent of the leucocytes and according to Moxter is to be found in the blood-forming organs, but the red blood-cells have been totally left out of account in the theories concerning the body's means of resistance, perhaps because Buchner's early researches gave such unpromisingly negative results. L. Heim (*Münch. med. Wochenschr.*, April 30, 1901) has lately made public some observations which tend to cast doubt on the propriety of this rigid exclusion of the erythrocyte from the protective cycle. In the earlier experiments the blood was subjected to preliminary taking in order to extract the contents of the cells which it has been supposed furnished nutrient media for the organisms, but it was found that this step was unnecessary and that the same results could be reached by using unchanged blood. If typhoid bacilli in pure bouillon culture are added to fresh defibrinated blood and the mixture is allowed to stand at body temperature, a gradual change in both the red cells and the bacteria takes place which reaches its maximum in about four days. The blood-cells first become pale and biscuit-shaped or take the thorn-apple form; later on they disappear entirely. The bacteria lose the power of motility and become aggregated in clumps which are not so typical, however, as in the true agglutination, and ultimately become swollen and granular.

In the presence of red cells, therefore, a destruction of typhoid bacteria takes place which differs from the ordinary bactericidal action of the serum in the time of its occurrence. What is commonly known under this designation appears during the first twenty-four hours of the presence of the bacteria in the blood, but then disappears and gives way to increased activity of growth, while here we have a second inimical influence which is due to anti-bodies which do not exist preformed in the body, but are manufactured only owing to the stimulus afforded by the vital processes of the micro-organisms, and this property does not become manifest till the power of the alexins has risen to its highest and fallen again.

The former view was that under favorable nutritive conditions, after once the first resistance of the alexins was overcome, the germs multiplied freely in the body till death occurred or a sufficient quantity of the specific antitoxin had been produced to make recovery possible. Buchner has expressed the opinion that all destruction of red blood-cells, as in burns, freezing and other conditions, is dangerous because it involves the setting free of just so much nutritive medium for bacterial growth, and this view is not contradicted but rather supplemented by these later observations. The contents of the erythrocytes may furnish suitable food for the bacteria or at least not prevent their development, but this is true only for a certain length of time after

which the invaders become subjected to degenerative processes. The danger to the body is not over, however, for it is probable that the bodies of the parasites and the substances extracted from them are toxic, while in addition the peril from the decomposing red cells lies not only in the increased growth of germs, but also in the fact that the development of the micro-organisms on broken-down body-cells may be attended by the formation of certain substances hostile to the body.

ETIOLOGY OF CEREBROSPINAL MENINGITIS.

FOR a number of years the bacterial origin of cerebrospinal meningitis has been a well-established fact. In 1885 Lichtenstein found a few cocci in the meninges of a case which had suffered from this disease, the organisms being single or grouped like the gonococcus in the white cells. Two years later Weichselbaum described a diplococcus situated solely within these cells, which, when inoculated into the meninges of dogs produced the lesions of meningitis. This he named the *diplococcus intracellularis meningitidis*. Since 1895, when Jäger demonstrated the presence of this germ in twelve cases, it has usually been observed by others in epidemic cases. For example, Councilman found it in 31 cases out of 35.

These are well-known facts, but the ordinary means of transmission of the disease is still a disputed point. Bacteria may enter the meninges (1) by direct communication from some cavity, such as the middle ear or nose, where they happen to be present; (2) by direct extension from an adjacent inflammatory process, such as mastoiditis or facial erysipelas; (3) from a distant process, such as pneumonia or endocarditis through the blood. Which route is followed by the diplococcus intracellularis is undecided, as is the medium by which it is conveyed.

The possibility that dust is an important vehicle is suggested by Buchanan (*Journal of Hygiene*, April, 1901) who has observed a marked relation between the occurrence of cerebrospinal meningitis and the character of occupation. The fact that it has been recognized chiefly among soldiers in barracks and among prisoners has led to the assumption that it is connected with defects in hygiene of their surroundings. Buchanan, however, has been unable to prove this point, and has been led to regard dust as an important vehicle and hence dusty occupations as a predisposing cause.

Three epidemics occurred at the Central Prison at Bhagalpur, Bengal, from 1897 to 1900, with 47 cases and a mortality of 68 per cent. Before the epidemics there had been in the prison one case in 1889, one in 1890, six in 1891, and one in 1892. Six months intervened between the first and second epidemics, and sixteen between the second and third, with irregular intervals between individual cases. In all epidemics the largest number were attacked in April, the time for hot and dusty wind storms. Eleven hundred persons were employed indoors where they were comparatively free from dust; 700 outside, at a dusty work. Of the 47 cases of the disease 44 were in persons engaged in dusty occupations, *e. g.*, grain husking, or other outdoor labor where they were exposed to dust storms; only 3 were among the 1,100 indoors. During the rainy season only 7 cases occurred, and these were in persons exposed to dust in cleaning grain, etc. No direct source of infection could be proven. There had been no case of cerebrospinal meningitis in the jail for four years before the first of those reported, none were known by other physicians to be in the vicinity, and the first patient had been in the jail for one year when taken ill. The first cases in subsequent outbreaks had been confined at least six weeks. The cases occurred in nearly all the wards. There was no evidence of direct contagion as the attendants were not attacked but the wards were slightly overcrowded.

These observations can hardly be held to prove the writer's point, the influence of dust as a vehicle for the diplococcus intracellularis, although they are extremely suggestive. If the dust out-of-doors was responsible, it seems strange that other natives in the vicinity were not affected, and the author distinctly states that no cases were known to exist among them. It is also noteworthy that during the recent campaigns in Northern China where dust storms were unusually severe, meningitis was very exceptional. Buchanan suggests that the germs may have remained in the dust collected on the roofs of the older wards. Some have found the diplococcus intracellularis alive after desiccation for ninety days; but Councilman, Mallory, and Wright noted that when dried on paper and kept at the room temperature in the dark, these bacteria were dead after from seventy-two to ninety-six hours. Although Buchanan's observations are not conclusive, the idea seems worthy of further investigation in view of the apparently strong evidence furnished by his cases.

ECHOES AND NEWS.

NEW YORK.

Gift to St. Vincent's Hospital.—By the will of the late Mrs. Matilda B. Brown, St. Vincent's Hospital is to receive $2,500.

New Building for the Babies' Hospital.—Plans were filed last Wednesday for the seven and eight-story brick hospital building to be erected at the northeast corner of Lexington Avenue and Fifty-fifth Street for the Babies' Hospital of New York. The building will be 80 by 40.5 feet and will replace those on the same site now owned by the hospital. It is to cost $90,000.

Jury Exonerates Physicians.—The trial of the action of Lucy V. Kellen against Dr. Morris Manges and Dr. Julius Rosenberg, which has been pending in the Supreme Court for the last nine days, resulted last week in a verdict in favor of the defendants. Miss Kellen charged that the physicians operated upon her without her consent, that the operation was unskilful and that they abandoned her after the operation.

The Smallpox Situation in Manhattan.—According to Dr. Dillingham, smallpox is increasing in Manhattan, and may not be stamped out for a year. These epidemics go in cycles. The last heavy outbreak of smallpox was in 1874-5; in 1875 there were 3,397 cases in Manhattan alone, out of a population of 483,788. Now with a population of more than 3,500,000 there were about 700 cases from December 28th to May 10th. May and June showed large increases —457 and 362, respectively, or more than for the preceding five or six months. Hot weather has no effect, directly, on smallpox; only vaccination represses it. There are from 500,000 to 1,000,000 persons in New York City who have neglected this precaution, and until vaccination is more general people might as well make up their minds to endure the scourge.

Summer Health Inspection.—Seventy-five physicians in the employ of the Health Department will begin, on Monday, a systematic, thorough visitation of the tenement-houses in all five boroughs. Ordinarily only fifty are employed in this work, and a start is not made before the middle of July, but the recent excessive heat caused a setting forward of the date. Practically all the tenements are in Manhattan and Brooklyn; those on the East Side will receive the closest attention. The physicians' duties are many and varied. Their mission is to look after any who may be sick and unable to afford a private physician; to advise mothers ignorant of proper methods of caring for children; to abate nuisances, or report them to the proper offices; to distribute tickets for outings given by St. John's Guild, and give away free ice tickets when needed.

New Maternity Hospital Incorporated.—The Manhattan Maternity Hospital and Dispensary has been incorporated to establish and maintain in New York City a maternity hospital, to provide hospital accommodations for women and children, to supply medical attendance for poor women at their own homes, and to maintain a training school for nurses. The directors are Daniel S. Lamont, Cornelius Vanderbilt, Percy R. Payne, Frank L. Polk, Moses Taylor, Harry S. Thompson and William Thorne.

Physicians and Collecting Agency.—A number of Brooklyn physicians sued by a collection agency which they had employed gained a verdict in the Second District Municipal Court, it being decided that a clause they had overlooked in the contract, binding them to pay a forfeit of $25 if they did not turn in the names of thirty debtors within a month, was against public policy.

Typhoid Fever in Brooklyn.—Health reports show that at present typhoid fever is at the low water mark in Brooklyn. Four cases were reported last week. This is a much smaller number than was reported during the corresponding weeks of previous years.

Deaths from Heat Prostration in Brooklyn.—The number of daily deaths from heat prostration during the recent elevation of temperature were 257 out of a total mortality of 930. While these figures undoubtedly include many cases in which other causes were largely contributory, they may be taken as a fair index of the part played by the heat in the greatly increased mortality.

Summer Corps Appointments for Brooklyn.—The following physicians have been appointed by the Health Board of New York to do summer corps work in Brooklyn: Drs. Timothy J. Regan, John A. Shields, James S. Slavin, Edward J. Megaw, Wm. McAnerny, John F. Kent, Christopher D. Kevin, Traverse R. Maxfield, Wm. E. Sullivan, James J. Bowen, Peter J. Curren, E. Rodney Fiske, Charles Ermentrout, John H. O'Neil, John H. Rob, H. P. Peck, Cornelia A. McConville, Novella G. Le Grand, Edson S. Chick. The term of service is two months, the salary being $100 per month. In addition to the regular duties attendant upon the position, they will be assigned to vaccination work as conditions may require.

Free Distribution of Pasteurized Modified Milk for Brooklyn.—The Brooklyn Children's Aid Society, working in co-operation with the Department of Health, began on July 6th the free distribution of Pasteurized modified milk. This milk is intended for sick children between the ages of two and four years and primarily for those suffering from summer diarrheal diseases. Two modifications are made, one being a lime-water and the other a barley-water mixture. These are prepared at the laboratory operated by the Department of Health and distributed from ten stations under the direction of the Aid Society. The distribution will continue until about September 6th and is in line with similar work

that has been carried on in Brooklyn during the past seven summers.

Smallpox in Brooklyn.—Since the advent of the heated term the number of new cases of smallpox occurring weekly in Brooklyn has shown considerable diminution. During the week ending July 6th there were reported and confirmed eight cases as against 38 cases for the week ending June 30th. The disease is evenly distributed throughout the city, nearly all sections being affected. The outlook, however, for the stamping out of the disease in the near future is encouraging.

PHILADELPHIA.

State Asylum to Be Enlarged.—At a recent meeting of the trustees of the State Hospital for the Insane at Norristown, Pa., arrangements were made for the expenditure of the $128,000 recently appropriated by the Legislature. Two buildings will be erected for the nurses at a cost of $100,000. At present the 300 nurses share quarters with the patients. It is reported that because of the overcrowded condition, 200 patients in each department are compelled to sleep on the floor. An infirmary for tuberculous patients will be built at a cost of $5,000. The remaining $2,300 will be used to complete other improvements. In the male department during the past month there were 15 deaths and 33 admissions; in the female department, 6 deaths and 29 admissions.

Mercy Hospital (Pittsburg).—Plans are in preparation for the addition of a surgical and medical ward building to cost $80,000. In addition to this, it is hoped to add a woman's hospital department, the estimated cost of which is $320,000 for the building alone. The preliminary work of the new ward addition will begin in a few days and part of the ground for the site of the woman's hospital has been secured.

Tetanus Following Vaccination.—A verdict of traumatic tetanus following vaccination was recently returned by a jury under Coroner Dugan concerning Maria McGinley, aged six years, whose death was ascribed by the parents to vaccine virus. Dr. David E. Henry, vaccine physician, who vaccinated the child produced samples of the points and said that out of 12,000 cases no bad results were obtained. The autopsy showed injury that might come from other causes than vaccination. On account of the lapse of time between the vaccination and the illness the Coroner's physician believes the virus was not at fault.

Criminal Malpractice.—Mrs. Catharine Bray was recently committed to await the action of the Grand Jury on the charge of causing the death of Mrs. Jennie Johnson. The autopsy showed that blood poisoning, due to a criminal operation, was the cause of death and the jury so found.

Public Baths.—Nearly half a million persons sought relief from the heat last week by resorting to the public baths. They were patronized by 117,452 men, 1,474 women, 331,235 boys and 6,567 girls.

An Emergency Hospital.—A hospital for the treatment of heat cases has been fitted up by Gimbel Brothers in the old Girard Hotel. They have furnished everything that will be needed by the city Medical Emergency Corps, which will have charge of the station. Soon after the doors were opened on July 4th five patients were brought from Independence Square, where the Chinese Minister was delivering the Independence Day oration.

Pittsburg Charity Hospital.—Property was recently purchased in East End, Pittsburg, at a cost of $100,000 for the erection of a new Charity Hospital. The deed will be given in October and the contract for building will then be let. The plans call for a five-story brick and stone building, 300x150 feet. It will contain about 500 rooms and will be one of the most complete and thoroughly equipped hospitals in the State. It will cost $500,000.

Effects of the Recent Extreme Heat.—The great number of prostrations and deaths due to the extreme heat of the last week has been a matter of daily news. The capacity of all the hospitals in the thickly populated portions of the city was overtaxed in caring for the sufferers. Aid was rendered by the Emergency Corps, by the police department, and by private individuals and firms, who, in some instances, furnished automobiles as ambulances to supplement or replace exhausted horses. The Pennsylvania and Episcopal Hospitals had their usual tents erected, and at some other institutions small tents were also put up. Systematic examinations of the blood are being made at short intervals in cases of both heat exhaustion and thermic fever to determine the condition present. Intravenous infusion of saline solution has been used in a number of cases with gratifying results. It was generally preceded by bleeding. In one hospital many of the cases of thermic fever were bled as soon as they were received, the patient being rubbed with ice meanwhile, and afterward put into the bath.

CHICAGO.

Hysterical Amblyopia.—At a recent joint meeting of the Chicago Ophthalmological and Neurological Societies, Dr. W. H. Peck reported four interesting cases of hysterical amblyopia. These cases presented many of the features of the disease. The patients had the characteristic concentric contraction of the fields of vision, also reversal of the color fields, spasm of accommodation, and blepharospasm, also absence of any demonstrable lesion of the fundus, with the ophthalmoscope.

Mydriasis.—Dr. Wm. H. Wilder reported a case of persistent mydriasis after the use of homatropine. Dr. C. P. Pinkard reported a similar case, which he saw many years ago in the

Boston Infirmary. The patient was a girl with an error of refraction, and homatropine was used. The pupils had not returned to their normal condition at the end of a week, and she was given pilocarpine to use, with instructions to return daily. She was finally admitted to the Infirmary, when eserine and pilocarpine were used for about a month. The patient then attended the out-patient clinic during the rest of his stay there, which was about eight months, so that she was under constant observation for about ten months. When he left the pupils were still dilated, with complete paralysis of accommodation. He thought the condition was due to hysteria. Dr. Casey A. Wood stated that, having had occasion to use homatropine, he looked up the literature and found half a dozen cases similar to the one reported by Dr. Wildner. He thought there was something more than hysteria connected with these cases, and that, perhaps, an organic element followed the use of homatropine. Cases of dilated pupils are not so frequently seen after the use of duboisine, atropine, etc., as after the employment of homatropine, but why he did not know.

Probable Tumor of the Pituitary Body.—Dr. Daniel R. Brower presented a patient for diagnosis. The boy was five years of age and weighed eighty-five pounds. He first came under the speaker's observation two months ago at the County Hospital, at which time he weighed ninety-two pounds. At a subsequent examination, made about a month ago, the boy weighed eighty pounds. He presented some comparative measurements and said that according to Dr. Christopher, who had done some original work along this line, the weight of a normal child of the same age was forty pounds, while this boy weighed over ninety pounds when first seen. The height of a normal child was forty-one inches, while that of this boy was forty-seven inches. Other comparative measurements were given of different parts of the body. He did not think the case was solely one of excess of fat. His attention was first attracted to the child by a marked vertical nystagmus. Dr. Hotz examined the boy two years ago and found atrophy of the optic nerve, with restricted vision and nystagmus. The atrophy must have been either congenital or developed from a central lesion. The field of vision is so contracted in the right eye as to be almost absolutely lost. There is likewise a little atrophy in the left eye. There is loss of both patellar tendon reflexes. Dr. Brower thought the case might prove to be one of tumor of the pineal glands or of the pituitary body. In the last number of Gould's Year-Book a somewhat similar case is reported, in which a diagnosis was made of tumor of the pituitary body, and at the postmortem examination it was found to be a tumor of the pineal glands. During infancy the boy was only the size of an ordinary child. The excessive growth began when he was three years of age and continued rapidly until seen by the speaker, at which time desiccated thyroid was administered. Since giving this agent, the weight of the boy has been reduced to eighty-five pounds.

Two Cases of Locomotor Ataxia.—Dr. Archibald Church presented two cases of this disease in males, and discussed briefly the Fraenkel method of exercises as a valuable adjunct in the treatment. In the discussion, Dr. Wood spoke of the involvement of the ear in tabes. He added a word or two of hopefulness regarding certain eye symptoms in tabes.

Diagnosis of Locomotor Ataxia.—Dr. H. B. Young of Burlington, Iowa, narrates two cases in connection with the diagnosis of tabes. He considers unreliable a diagnosis of locomotor ataxia based upon optic nerve atrophy and absence of knee-jerks, if no other manifestations are present. Something more is required and, while the profession is looking for it, he urged adherence to the teachings of Schmeichler.

GENERAL.

Resurrection of "Vratch."—This able Russian medical journal is to continue under a new title in pursuance to the wishes of the late editor, Dr. Manassein. It is to be called the "Russian Doctor" instead of "Doctor." Dr. W. Podwyssotzky, professor of Pathology at Odessa, is the new editor.

Physician, Not Horse Doctor.—A physician and surgeon has not the right to practise as a veterinarian. Such is the decision given by Judge W. G. Cochran in a case in the Douglas County Circuit Court, in which Dr. Barbour has sued Mell Crews for medical attention given to Crews' racer, A. J. Glick, which was injured while racing at Dubuque, Iowa. Barbour presented a bill for $258 and Crews contended that this amount was excessive, but paid $100. Barbour sued for the remaining $158, but lost the suit, as the Judge decided he had no right to practise as a horse doctor.

University of California.—A chair of anatomy has been established at the State University of California and Dr. Joseph Marshall Flint, instructor in anatomy in the University of Chicago and graduate of Johns Hopkins University has been appointed to the professorship.

Manila and the Plague.—The plague situation in Manila remains about the same, and no marked increase in the number of cases has occurred. During the week ended May 25, 1901, there were reported 29 cases—Chinese, 20; Filipinoes, 9—with 25 deaths. During the same period 8 cases of smallpox and 175 deaths from all causes were reported. One other new case of plague has occurred in Cavite, making a total of 2, with fatal results in both. Another case has also occurred in Santa Rosa.

Obituary.—Dr. Henry C. C. Maisch, of Philadelphia, died July 1st, aged thirty-eight years. After completing his education in Germany, Dr. Maisch was connected with Clark University, Worcester, Mass.; later he held a profes-

sorship in the Illinois College of Pharmacy in Chicago. For two years he was professor of materia medica and botany at the Medico-Chirurgical College, but resigned last year.

Dr. Martin H. Williams of Philadelphia died June 30th, aged thirty-nine years. For many years he was connected with Jefferson Medical College and Hospital in various capacities.

CORRESPONDENCE.

THE "HAND-STONE" IN SURGERY.

To the Editor of the MEDICAL NEWS:

DEAR SIR: In the great electric furnaces at Niagara is now manufactured a new product of synthetic chemistry, by aid of intensest heat; it is called by its discoverer carborundum. It is composed of tiny purple crystals hard enough to scratch sapphires, almost as hard as diamonds and even more indestructible. To produce it carbon is made to combine with silicon, using for the purpose coke and white sand, and at a heat of about 7,000° F., produced under the intensity of a current of 7,500 amperes, continued for some thirty-six hours.

This substance, carborundum, is finding an immense field of usefulness in various ways, but it is only recently that it has occurred to any one to apply it to the surgeon's needs.

The *bête noire* of the surgeon has been, is, and is likely to be, the skin. How to cleanse this, how best to free it from its microbic population with the least irritation, is continually being discussed, and the advent of rubber gloves has not lessened the interest; for though these have in my judgment come to stay, and those who oppose their use in ordinary aseptic operations are steadily lessening in number and influence, we must as carefully sterilize our hands now as before their coming, for at any moment a finger may be torn or pricked, exposing the wound to instant infection, otherwise.

I do not think the ideal method of sterilizing either our own skin or that of the patient has as yet been reached. The various chemicals used thus far are one and all irritant to most skins, or else are too slow in action to be considered ideal. However, my object is not at present to discuss them. One thing is certain; mechanical cleansing —while not in itself enough—is certainly the chief thing; and sufficient hot soap and water with friction of the right sort, for a reasonably long time, will go a long way toward the goal of absolute cleanliness in a surgical sense.

Heretofore, brushes have been considered as almost essential, although it has long been known that, in some regions, by the digging quality of the bristles the "submerged tenth," otherwise quiescent and fairly well-behaved microbes, dwelling in the deepest layers of the epidermis, may be stirred into a vigorous nihilistic activity. Still, as an effective loosening and removal of the superficial layers of the epithelium is obligatory and the brush has continued in use.

To-day, due to the ingenuity of Mr. F. A. Reichardt, of New York, we have a substitute for the brush which bids fair to become a favorite with the profession. This he has called the "hand-stone." It is molded from the carborundum crystals just described, first crushed to powder, and then resubjected to intense heat in its present shape. I have tried it sufficiently to be willing to speak confidently of its qualities. One employs it just as one does the brush or the pumice-stone, using an abundance of soap and water; but it has certain advantages over both. It does not dig in an unseemly way like the brush, and it is certainly more effective than pumice-stone, and also stands boiling or steaming perfectly well, of course. In fact, nothing short of dropping it upon a hard surface can injure it or affect it adversely in the least, and years of wear would leave it practically new. Use it gently; hard rubbing is unnecessary with it. The absolute sharpness of the almost microscopically small crushed crystals which compose the "hand-stone" enables the operator to file away, as with a file of extreme fineness, the surface layers of epidermis, down to the depth required, and the silken softness of the feel of the skin thereafter is really in noticeable contrast with the roughened condition often observable when the other means which I have mentioned have been used.

The particular pointed shape given the "hand-stone" is selected by the maker as enabling the user to fit its surface to any depressions or inequalities of the body. As yet, a means of making it reach the extreme angle beneath the finger nails has not seemed practicable, for this would require a very thin edge. But elsewhere it is all that can be desired for its special purpose, and I would suggest that surgeons boil one with their instruments, and then use it with, for instance, a lysol solution, in that final cleansing—or rather re-cleansing—of the patient's skin which we always employ a moment before operating.

ROBERT H. M. DAWBARN.

OUR LONDON LETTER.

(From Our Special Correspondent.)

LONDON, June 29, 1901.

THE NATIONAL HOSPITAL FOR THE PARALYZED AND EPILEPTIC—REPORT OF THE COMMITTEE OF INQUIRY—A VICTORY FOR THE MEDICAL STAFF—THE END OF THE "ANCIEN RÉGIME"—ABOLITION OF THE SECRETARY-DIRECTOR—THE TUBERCULOSIS CONGRESS—PROGRAM OF FESTIVITIES—KOCH'S ADDRESS—IS HE GOING TO STARTLE THE WORLD AGAIN?

A FEW weeks ago I gave a short account of a quarrel between the doctors and the lay governors of the National Hospital for the Paralyzed and Epileptic which was convulsing the medical world of London and scandalizing the public. Briefly, the matter in dispute was, Should the medical staff have a voice in the management of

the hospital? Or should they be merely the executive, carrying out the behests of the Board of Management, or rather of an autocratic official entitled the Secretary-Director, concentrating in his own single person the administrative authority which he was supposed to represent? The demand of the medical staff, which includes several men of worldwide reputation, for some share in the government of the institution whose reputation they have made was obstinately and even insolently refused by the Board of Management; and when they made a formal complaint to the whole body of governors about definite instances of mismanagement, such as insufficient quantity and inferior quality of food, deficiencies in the nursing arrangements, etc., the Board appointed some members of their own body to inquire into the charges. Naturally the result of the inquiry was a declaration that all was for the best in all possible hospitals. The medical staff, however, insisted on an impartial inquiry by an independent committee, and at a meeting of the governors on March 23d it was decided that such a committee should be appointed. It was to include "at least one physician or surgeon, one eminent lawyer, one man engaged in commercial or financial pursuits, one man experienced in hospital management, not being a medical man, and one other person, none being members of the Board or Staff." The Committee comprised Sir Edward Fry, a late Judge of the High Court, a distinguished lawyer by no means likely to be biased in favor of the medical profession; Lord Wolverton; Sir W. W. Karslake, a King's Counsel learned in the law, as the official style runs; Mr. Timothy Holmes, formerly Surgeon to St. George's Hospital and a recognized authority on hospital affairs; Mr. Cecil Henry Russell, and Mr. John Danvers—both of them doubtless good men and true, but of whom the present deponent knoweth nothing. The Committee has made a thorough inquiry and its report, of which I have been privileged to see a copy though it has not yet been issued to the press, is a complete vindication of the medical staff, and a crushing condemnation of the system of government or rather misgovernment which has caused the trouble. The Committee recommends that the representation on the Board asked for by the staff should be granted, and what is particularly satisfactory they brush aside with contempt the objections to this concession put forward by the Board. The character of these may be judged from one or two instances. The Board affected a great fear of the evil influence that medical members might exercise by making the scientific element in the hospital predominant; this, they pleaded, would tend to subordinate the immediate benefit of the patients to the pursuit of medical knowledge. In proof of this it was darkly hinted that in the case of one child "the sufferings of the patient had been prolonged in the interest of medical science." The case referred to is understood to be one of microcephaly which some years ago was kept in a considerable time in order that the effect of linear craniectomy might be fully tried. This charge, at once malicious and foolish, was shown to be without foundation. Then it was insinuated that the religious functions of the Chaplain were made "very secondary to the medical services!" The Committee were able to satisfy themselves that the medical staff never interfered in any way with the spiritual ministrations of the reverend gentleman. There is a note of scorn in the conclusion of the Committee that they can find no foundation for the fears entertained that the character of the hospital as a religious and philanthropic institution would be imperiled by the presence of two medical men on the Board of Management. One cannot help feeling that the dread which the Board professed to feel lest the presence of two doctors should lead to the complete overshadowing of the other members of a Board of twelve is an unconscious testimony to the intellectual superiority of the medical staff.

With regard to the Secretary-Director, the *causa teterrima belli,* the Committee express a decided opinion that there was no place for such a functionary in the machinery of a well-organized hospital; and that, even if there were, Mr. Burford Rawlings was the wrong man to fill it. It was abundantly proved that the Board of Management had practically left the conduct of affairs to him. He was a member of the Finance and House Committees, at the meetings of which *one* was a quorum, and very often the quorum was the Secretary-Director. He therefore ruled the hospital virtually as a despot, and in his attitude toward the medical staff he "assumed the god" and "seemed to shake the spheres" by his nod. It was shown that he usurped the functions of the medical officers and that instead of limiting himself to the discharge of the duties entrusted to him, he had on many occasions, in the language of the report, "amplified his jurisdiction beyond its legitimate bounds." The Committee recommend the abolition of the office of Secretary-Director, which places in the hands of one man powers that it would require a peculiar combination of qualities (which, the Committee plainly say, is not possessed by Mr. Rawlings) to exercise without abuse

The practical outcome of the inquiry, therefore, is a victory for the medical staff and a signal defeat for the Board of Management. The Secretary-Director is left, in an official sense, dead on the field of battle. But I understand that the medical staff will not be satisfied with this. They thirst—of course, "tropically," as Hamlet says—for the blood of the Board of Management. They wish to make a clean sweep of their enemies, and to enter on a new era of scientific fruitfulness under the Saturnian reign of a more enlightened government.

The underlying cause of the whole trouble was the fact that some of the more influential members of the Board, including the Chairman, are strong antivivisectors, while some leading members of the staff, like Ferrier and Horsley, have

won distinction by experimental research. This is the explanation of the attempts of the Board to make people believe that if the medical staff had a voice in the management of the hospital it would become more a laboratory than a place for the treatment of disease.

The Committee of Inquiry appear to contemplate a complete change of government; for in their Report they distinctly state that the Secretary-Director only acted in the spirit of the instructions which he received from the Board of Management, and that on them, therefore, rather than on him rests the responsibility for his misdeeds. It is satisfactory that the National Hospital, of which we are very proud here, is not to fall from its high estate and become a happy hunting ground for the humanitarian faddist.

The prospects of the forthcoming Congress on Tuberculosis grow brighter as the time of meeting draws nearer. Some 1,200 adhesions have been received up to the present, and they continue to come in daily, so that there can be little doubt that the number will exceed 2,000. Money also flows in a steady stream; the Treasurer has now $23,000 in hand and he expects the figure to rise a good deal higher. The Congress is to be opened on Monday, July 22d, by the Duke of Cambridge, as representing the King. The Duke of Connaught will be prevented by his military duties from performing that duty as had been arranged. In addition to the customary banquet, there will be receptions by various great officers of the Congress, by the Lord Mayor, by the Earl and Countess of Derby and others. A river party is to be given by Sir John Whittaker Ellis, a former Lord Mayor of London; a garden party by the Duke and Duchess of Northumberland; and one by the Ladies' Reception Committee in the beautiful gardens of the Royal Botanic Society, Regent's Park.

I have already sent you the most important features of the scientific programme, and have only to add that Lord Lister will take the chair when Koch delivers his address on Tuesday, July 23d. The address will deal with the prevention of tuberculosis considered on the analogy of other infective diseases such as smallpox, cholera, plague, hydrophobia, rinderpest, malaria and leprosy, which can be to a certain extent successfully prevented. The principal question which Koch will discuss is whether what has been done up to the present for the prevention of tuberculosis and what is likely to be done in the near future correspond to the etiological conditions of the disease; and how far steps should be taken toward the adoption of more thorough methods of treatment. It may be said of Koch, as it was said of Dupuytren, that his motto might be *"Faire autrement."* He has, as far as so godlike a man can share in human weakness, the instinct of sensationalism, and from the somewhat mysterious foreshadowing of the lines of his address which he has communicated to the officials, one may gather that he intends to say something that will startle the Congress. After all I hear Madame will not accompany him, a change of plan which has relieved the minds of some of the organizers by removing the danger of social complications which might have slightly ruffled the perfect smoothness of the proceedings. But nothing short of the sudden death of the King, a French invasion, or a cataclysm of Nature, can now wreck the Congress.

EXUDATES INTO THE VITREOUS—PARALYSIS OF THE THIRD CRANIAL NERVE WITH UNUSUAL COMPLICATIONS — BILATERAL SYMMETRICAL CORNEAL OPACITIES—ERYTHROPSIA—EYE INJURY DUE TO LIGHTNING.

L. BUCHANAN, at the Ophthalmological Society, June 13, 1901, read a paper on the inflammatory exudates into the vitreous chamber of the eye, illustrating his points with lantern slides made from his preparations. He said exudation into the vitreous in cyclitis was primarily formed in the pars ciliaris retinæ and more especially in the non-folded portion of it, but soon the fibrous stroma of the ciliary body and the retina took part in the production of the inflammatory exudate. The exudate was seen in fresh specimens hardened in 5-per-cent. formalin as white flocculent masses. It might be divided into zones, which from the ciliary body inward are as follow: (1) Fibrous zone; (2) fibrinous zone; (3) fibrinocellular zone. The formation of fibrous tissue usually begins early, possibly as early as the eighth day. Its origin appears to be some action of certain oval nuclei on the fibrin which then rapidly becomes fibrous tissue. The cells which formed the exudate at first formed masses on the non-pigmented parts of the pars ciliaris retinæ and could assume various characters. That all these cells are not derived from the endothelium is shown by bleaching and re-staining, when many cells could be seen migrating from the deeper to the more superficial layers. In the retina were also found similar evidence of migration. The cells thus exuded to the surface passed to a greater or lesser depth into the vitreous chamber where it could be seen that degeneration to different degrees had taken place, the nuclei often disappeared, but no evidences of mitosis could be made out. Fatty degeneration and later a further migration of nuclei occurred, which finally found their way back into the lymphatics. A fibrinous cyclitic membrane was thus left very fatty and highly vascular. The fat was absorbed and the vessels gradually constricted, so that finally an avascular fibrous tissue layer was left which gradually contracted and distorted and deformed the eye and then destroyed it. The last stage was the formation of true bone. Spherical globules were formed which grew, forming a solid mass penetrated by blood-vessels and finally became converted into bone. These bone corpuscles were probably fibrous tissue corpuscles. The

bone contained cavities lined with osteoblasts, blood-vessels, fat and fatty-acid crystals.

P. H. MULES recounted a case of paralysis of the third cranial nerve with unusual complications. The patient was a seventy-five-year-old man, who for several days had been feeling ill and proceeded to doctor himself by the following original and energetic plan. He took half a box of wind pills and feeling no better added a variety of others. He then took two ounces of tartar-emetic solution which provoked a two-day vomiting. When the vomiting had ceased, he proceeded to use on the forehead and scalp of his aching head various applications which are used chiefly for veterinary purposes. As he still continued to grow worse, Mr. Mules was called in. The edematous scalp was incised and ten grains of calomel given. The next day the patient was better, although sloughs covered the scalp and there was severe pain. It was then noted that there was paralysis of the third nerve. Seventeen days later the scalp had healed entirely, but the paralysis remained. The cause of all the trouble seemed to be a herpes of the fifth nerve. This was the cause of the patient feeling ill in the first place. The vesicles had never been seen, because the applications had caused so widespread destruction of the tissue. As a sequel the paralysis of the third nerve appeared.

P. H. MULES also reported a case of double symmetrical corneal opacity of eight years' standing. The apices of the lesions were at the pupil and the bases at the corneal margin. Their growth had been very slow and there was a vertical slit in each at about the pupil. One was scraped and the other cut away with a thin knife. The functional results had been very good. G. A. Critchell in the discussion stated that for seven years he had cared for a similar case in which the opacity began at the periphery. At the present time the pupils had still escaped, therefore he had not done any operation.

W. H. R. RIVERS described a form of erythropsia which appeared as a bright red border around a white object after strong illumination of the eye. This phenomenon might be regarded as a link intermediate between the ordinary forms of erythropsia and the transient red border seen about a white object and described by Shelford Bidwell. It was shown that this erythropsia of Bidwell, the artificial erythropsia of Fuchs and clinical erythropsia, such as occurs after removal of the lens, are closely related. The causes of all erythropsia were then considered and on the whole were shown to be due to coloration by the light stimulating the retina with blood. Such might be produced in several ways: (1) By transmission through the sclerotic; (2) by internal reflection from the eyeballs; (3) by transmission through the anterior layers of the retina. The experiments of Birckhoff show that erythropsia may occur when light is prevented from passing through the anterior periphery of the eye; but this does not exclude the third source of redness above mentioned.

M. T. YARR gave the history of two cases of injury to the eye due to lightning in South Africa. While encamped in the Orange Colony in March, 1900, they were exposed to a violent thunder storm. Major H.'s tent-pole was struck and at the same time he felt a tingling down the right side of his face and right arm. He became partially unconscious, but soon recovered; the tingling persisted for some days. Four months later he discovered that he was practically blind in the right eye and he was invalided to the base hospital. There were several large hemorrhages and patches of atrophy in the retina between the superior and inferior temporal veins, with a few scattered and much smaller hemorrhages in the periphery, some engorgement of the veins, pallor of the disc and contraction of the arteries. The left eye was normal. R. C., private, employed on telephone duty at Belfast, Transvaal. In October, 1900, his instrument was struck by lightning while he was sitting at his operating-table. He fell and could not see when he regained his senses. He suffered no bodily injury, but his instrument was bent. The next day he could distinguish light and darkness, and later count figures with the left eye. There was an extensive detachment of the retina in the right eye, running in wavy white lines inferiorly. The left eye showed a detachment spread over a wider area. The vision had been previously normal.

SOCIETY PROCEEDINGS.

AMERICAN MEDICAL ASSOCIATION.

Fifty-Second Annual Meeting, Held at St. Paul, Minn., June 4-7, 1901.

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

FIRST DAY—JUNE 4TH.

Address of the Chairman.—Dr. Henry P. Newman of Chicago, in reviewing the advances in obstetrics and gynecology during the past year, accorded spinal cocainization first consideration. The consensus of opinion is that it is not applicable to children nor to major pelvic operations in sensitive women. The appearance of a patient during such major operation closely resembles one in a condition of shock. There have been six deaths recorded against the procedure. It is unreliable in obstetrics, because it cannot be timed to exert its good effect when most needed. There is no relaxation of muscular tissue while the patient is under its influence, and as that is necessary for the performance of most obstetric and gynecological operations, its field of usefulness is very much limited. In reviewing the cancer parasitic theory, one is struck by the large amount of work done in this field by American observers. At present, the only means of preventing uterine cancer is by removing all

abraded surfaces in the cancer bearing areas. In these cases the organs should be removed by the vaginal route. Ovarian transplantation has become a fixed operation and the honor of introducing it is due to Morris of New York. It is definitely settled that the ovaries can be transplanted anywhere in the pelvic peritoneum and still functionate.

Accidents and Complications of Pelvic Surgery.—Dr. John B. Deaver of Philadelphia, said post-operative adhesions are the most troublesome conditions that the surgeon is called upon to treat. The lower sigmoid offers the greatest perils, and this portion of the bowel is frequently torn. This is due to the immobility of the bowel at this point. Where the omentum is adherent it should be divided between ligatures. If a cyst or innocent tumor is adherent and inseparable from bladder or bowel it is advisable to remove as much as possible and to sear the remainder with the cautery. Collections of pus in the pelvis should be operated upon from above. It is impossible to deal with adhesions when the operation is done from below. Every woman who has borne children has a laceration of the cervix, yet not one in fifty should be repaired, unless in such cases there is a family history of cancer.

Dr. E. M. Ricketts of Cincinnati, said that in puerperal infection the pus should be evacuated by vaginal puncture or incision.

Post-operative Intraperitoneal Hemorrhage.—In this paper Dr. A. H. Cordier of Kansas City, Mo., said the most frequent cause of post-operative hemorrhage is the slipping of the ligatures. Catgut is an unstable ligature on large pedicles, because it is very apt to slip and when rapidly absorbed may allow fatal hemorrhage. In the only case in which the author employed it, fatal post-operative hemorrhage resulted. Silk is the best ligature for abdominal work. The tendency to post-operative bleeding is much increased by the use of the Trendelenburg position, because when the patient is lowered to the horizontal posture blood-pressure is increased and many vessels are reopened. The symptoms of hemorrhage and shock are the same. If the patient leaves the operating-table in good condition and within an hour or so shows symptoms referable to either of these conditions, it is better to open a suture, insert a pair of artery forceps and see if there is any bleeding. In all doubtful cases, where the wound is oozing, it is better to insert a rubber tube for twelve hours after the operation.

Dr. Howard A. Kelly of Baltimore said that he uses fine silk for ligatures and, provided everything be sterile, there is no trouble from the ligature. He had seen a fatal post-operative hemorrhage occur eight days after operation, which on autopsy was shown to have been due to absorbing of the catgut ligature. It is his custom to employ two ligatures on every large vessel. Careful inspection of the field after the operation should be made. If there is any doubt as to whether or not bleeding is going on it is better to open and see. The vessels should be caught first by a finger or forceps and clamped, and after that one may clean out the blood from the pelvis. Dr. McMurtry of Louisville does not believe that the ligature material has anything to do with the slipping of the ligature. He clamps the broad ligaments first in order to get rid of tension and then ties the vessels. The simple secondary operation of opening a wound of this kind is very much more serious than the most severe primary operation. Dr. H. O. Marcy of Boston advises that a suture be employed in these abdominal operations in addition to ligature. Kangaroo tendon is the best material. Dr. F. H. Wiggin of New York said that many of the secondary operations that he has been called upon to do were the result of silk ligatures. He uses fine chromicized catgut and has never had them slip. He also sutures. The method of tying is responsible for many failures. A single knot should be tied first and a double knot afterward.

Elimination of Peritoneal Infection and Prevention of Surgical Peritonitis.—Dr. J. G. Clark of Philadelphia from an analysis of 1,700 cases and various experiments draws the following conclusions: The peritoneum has an enormous absorbing function, taking up from three to eight per cent. of the entire body weight in one hour. (2) Minute bodies are carried in a short time by mediastinal lymph-glands and vessels into the blood by which they are quickly distributed to abdominal glands and bone-marrow. (3) These granular bodies are first largely carried as free bodies swept by the current, but later leucocytes act as carriers. (4) After the introduction of micro-organisms into the peritoneal cavity, there is a great decrease in their number within the first hour, both by intraperitoneal destruction and by rapid absorption into the general circulation, wher they are dealt with. (5) Therefore there is no possibility of limiting free infectious matter to any part of the peritoneal cavity by mechanical means. (6) Vigorous streptococci which remain behind develop within six hours a repellant quality for leucocytes and the lethal combat is therefore well under way before drainage, as ordinarily employed, can possibly have any beneficial action. (7) A moderate number of even virulent organisms carried by blood to the lungs, etc., may be eliminated without the least harm to the patient, whereas if the same amount of infection is retained it would generate others and overwhelm the patient. (8) In most cases drainage is useless. (9) The patient is greatly stimulated by the intra-peritoneal use of the decinormal salt salution and is better able to resist infection.

Dr. Kelly of Baltimore said that he never

uses drainage in abdominal work, except in general peritonitis due to appendicitis. At times gauze is used to sequestrate cavities, but is generally removed within twenty-four hours. Dr. Wiggin believes that the saline solution prevents adhesions between the intestines. He has used this method for nine years with the happiest results.

A New Method for Extirpation of Cancer of the Rectum.—Dr. M. D. Mann of Buffalo, N. Y., read a paper on this subject. For growths too high to be reached by vagina or rectum the following procedure had been successfully applied in three cases. The patient is placed in the Trendelenburg position and an abdominal incision made; the rectum is then clamped just above the growth, pulled out of the way, the growth removed and a Murphy button used as a means of anastamosis. Excellent union was obtained. Dr. J. W. Bovée of Washington suggested that the uterus be removed in these cases, thus affording more room.

SECOND DAY—JUNE 6TH.

Atresia Hymenalis.—Dr. O. Thienhaus of Milwaukee showed a specimen of this condition and said that the presence of hematosalpinx in it proves that this atresia is of inflammatory origin. Any of the infectious diseases may cause it. Gonorrhea in the infant often affects the vagina and is the commonest cause of atresia. If a hematosalpinx is present it must be removed by abdominal section. Simple vaginal incision is fatal in 70 per cent. of the cases. This is due to the sepsis that almost invariably as follows.

Immediate and Remote Result of Conservative Surgery.—Dr. A. Goldspohn of Chicago read this paper. He said that in a series of 97 cases of follicular and cystic degeneration of the ovary treated by excision and ignipuncture, ten pregnancies occurred. Satisfactory results as far as the symptoms were concerned were obtained in but one-half of those treated per vagina. In all of the cases done from above the results were perfect two years after operation. The method by inguinal incision is preferable in those cases that do not have extensive adhesions. In all patients not near the menopause and free from dyscrasia, some part of the ovary should be preserved. Asepsis is a *sine qua non* to success. Fine absorbable material should be employed as a suture. The incision should be large and preferably done through the abdominal wall.

Dr. Bovée stated that if the ovary is extensively diseased it should be removed entirely. It is safer to remove the entire tube than a part of the same. The cases treated by excision or puncture are generally troubled later by the adhesions that form in these places. A premature menopause is not as troublesome as the stormy menstruation that occurs in these cases.

Electrothermic Hemostasis.—Dr. A. J. Downes of Philadelphia in a paper with this title, considers hemostatis by electricity the ideal method in abdominal surgery, especially in appendectomy. The instruments devised by the author for this purpose consist of an angiotribe and hemostatic forceps, provided with an iridoplatinum strip in the jaws, and connected with a storage battery. In a series of cases examined postmortem, no trace of vessels could be found in the stump.

How Shall We deal with Uterine Myomata? Dr. E. E. Montgomery of Philadelphia believes that thyroid extract exerts a special influence on the epithelium of the uterus. It stops bleeding and relieves pain both in normal and carcinomatous uteri. Large doses are required and these are rarely well borne. Fibroids ordinarily should be removed by enucleation. Submucous fibroids can be removed by vagina after dilating or splitting the cervix. It is seldom necessary to remove the uterus.

Carcinoma of the Cervix Uteri.—Dr. J. M. Baldy of Philadelphia in his paper upon this subject said that according to the surgery of the present day cancer of the cervix is practically incurable. If we analyze all statistics, counting all our cases, less than five per cent. have been reported as cured. In the past there has been too much stress laid upon microscopic findings and too little upon clinical experience. Hemorrhage and progressive loss of flesh and strength are the earliest symptoms and they are always present. Any show of blood appearing after one year after the menopause, with no history of injury, has in his experience almost invariably been due to cancer. A few drops of blood after coition or constipation, or any slight exertion in any woman, calls for an examination. It is extremely rare to find any other cause except cancer.

Dr. Wiggin said that if a case is seen within six months from its inception, there is a good chance of recovery by surgical means. We should not wait too long for the report of the pathologist, if the clinical symptoms are marked, because in some cases within a few days the case is beyond recovery. Dr. E. Reis of Chicago described his method of extirpating the uterus and appendages together with all the glands in the pelvis and stated that, although his primary mortality is 20 per cent. there has been no recurrences in any of his cases. The operation is not as difficult as might be expected.

Ovarian Surgery.—A paper on this subject was presented by Dr. A. Palmer Dudley of New York. It is very rare that total ablation of uterus and appendages is necessary in pelvic diseases. Out of 190 cases of conservative operation there had been no failures, and the women are perfectly well to-day. Conservative surgery is only suitable for young persons during the child-bearing period and those in good circumstances who can afford to rest for

some months after the operation. Out of 128 of these cases that have been followed 28 pregnancies have occurred. He has performed intra-uterine implantation of the ovary six times. One of the horns of the uterus is split and the ovarian graft, still attached to its own ligaments, is suspended in the uterine cavity and stitched to the mucous membrane. In this way it is nourished by its own vessel and also by the mucous membrane of the uterus. The patient menstruates and thus the evils of the artificial menopause are mitigated. Dr. J. Riddle Goffe of New York said that he has done the conservative operation a hundred times and in eleven instances pregnancy has followed in women that were previously sterile. He advised that the operation be done through the vagina.

Incisions Appropriate to Different Renal Operations.—Dr. Kelly said that the ordinary incision for approaching a kidney posterially cuts across some of the nerve trunks and thus often causes an area of anesthesia over the hip. By anatomical demonstration it was shown that an incision over the superior oblique triangle, beginning over the last rib, running down obliquely along the erector spinæ, and carried only through the skin and fascia was most advantageous. The fascia is then incised and the fatty capsule of the kidney gradually pulled out piece by piece. In this way the kidney is not injured. If the kidney is diseased and it is necessary to remove it, the incision should be made lower down, reaching to the crest of the ilium. The fascia should be cut and the muscles separated exactly in the same manner as in the McBurney incision for appendicitis.

THIRD DAY—JUNE 7TH.

Surgical Treatment of Retroversion of the Uterus.—Dr. Franklin B. Martin of Chicago presented this paper. After having tried various modifications of the ordinary Alexander operation, the author concludes that none of them secure perfect results. Hence, the following operation was devised: In cases of simple retroversion without adhesions the ordinary incisions are made as in the Alexander operation. A forceps is then passed from one side under the skin and fascia to the opening on the other side. The ligament is now grasped in the jaws of the forceps and brought through to the opposite side. The two ligaments are then tied in a knot and this knot is pushed under the skin and superficial fasia. Sixty-one cases have been done by this method with perfect results during the past five years. Among these cases six pregnancies have since occurred without any evil results. By this method uniform shortening of the ligaments is secured, and permanent and strong fixation is insured.

Retrodisplacement of the Uterus.—Dr. Emil Ries of Chicago read a paper on this subject. The vaginal route is superior (1) because it exposes a limited area; (2) the shock and danger of infection are much less; (3) it requires less handling of the intestine and less adhesion results; (4) there is no visible scar; (5) there is no ventral hernia; (6) the time of detention in bed is less and the after-treatment very simple. Vaginal fixation as ordinarily employed is a failure, because, if the uterus is fixed too close to the anterior vaginal wall, there will be trouble if pregnancy should follow. On the other hand, if loosely attached, a return of the displacement is very common. With other methods of shortening the round ligaments, the uterus is held by unstable adhesions and kinking of the Fallopian tube is quite common. In the author's method the ordinary anterior vaginal incision is made, the uterus and appendages are brought out, the round ligament is next detached from its peritoneal covering by a blunt dissection, a catgut ligature is then attached to each ligament about one inch from its insertion into the uterus. On the anterior surface of the uterus on a level with the tubes a tunnel one inch long is made through the uterine tissue by means of artery forceps. A round ligament on one side is pulled through this tunnel by means of the catgut ligature attached to it. The same thing is done on the opposite side. The ligaments thus are made to cross one another in the tunnel. Each of the ends are anchored at the point of exit of the loop from the tunnel on each side. The wound is closed in the usual manner. Within a week the patient leaves the hospital. Perfect results have been found in all the cases examined one year after the operation.

Dr. Goffe of New York said in discussion that the uterosacral and uterovesical ligaments are the main supports of the uterus. If the cervix could be brought well up in the hollow of the sacrum by shortening the uterosacral ligament, we would have the ideal method. This is impracticable at present. In his own operation he makes a vaginal incision, sutures a loop in the round ligament and fastens the loop to the anterior surface of the uterus. If silk is used as a suture, failure is not likely. Dr. W. H. Humiston of Cleveland believes that in a simple retroversion, by a thorough curetting and the use of a suitable pessary for eight or ten weeks, one can cure most of these cases. Dr. Kelly has had relapses in but 2 per cent. in 600 cases of abdominal fixation done by the method described by him. Forty-three patients became pregnant out of a series of 214. There was no trouble during labor in any of them.

Position of Patient During Delivery.—This paper was read by Dr. W. D. Porter of Cinnati, O. In the ordinary method of delivery, with the patient on her back, fecal matter often enters the vagina and is a frequent cause of

septic infection. The author prevents this in the following manner: The patient is laid across the bed with her hips well down to the edge with her legs extended; two assistants are employed to hold the legs, but in some cases the backs of two chairs may be utilized. The operator sits in front between the legs and is thus able to control the head and perineum perfectly because the patient cannot change her position.

Obstetrics as It Is and as It Should Be.—Dr. E. Gustave Zinke of Cincinnati said we should encourage the confinement of all women, no matter what their circumstances may be, in maternity hospitals, because no one can be prepared for all emergencies in a private house. The patient should be delivered by the family practitioner. It saves the physician's time and also offers greater protection for the patient than at present.

Puerperal Sepsis.—Dr. J. F. Moran of Washington, D. C., in this paper said, that the streptococcus is the commonest cause of severe septic infection. In cases due to streptococcus the pulse rate is high and out of proportion to the temperature curve. The constitutional symptoms are also more marked than would be expected from the height of the temperature. In staphylococcus and colon infection the temperature may be high, but the pulse is lower than in streptococcus infection. Marked beneficial results were obtained in several cases of pure streptococcus infection by the author from the use of antistreptococcus serum.

The Curette in Obstetric Practice.—This paper was read by Dr. H. D. Fry of Washington, D. C. As a general rule the curette should be employed only in those cases in which we cannot use the fingers. In infection by streptococci a protective zone is formed beyond the limit of the exudate and the general system is usually protected. If this be broken down by the curette a general infection results. If the infection be due to saprophytic organisms, a foul-smelling discharge occurs and here the use of the curette is indicated. The streptococcus infection is seldom accompanied by a foul-smelling discharge and this is a rough means of differentiating between them. If one is in doubt cultures can easily be taken and most cases can safely wait twelve hours for the result.

Streptococcus Infection Following Labor.—This report was read by Dr. W. Humiston of Cleveland, O. The case was drained by the method of opening into the pouch of Douglas and inserting gauze therein. The streptococcus, staphylococcus and colon bacillus were found in the peritoneal exudate. A satisfactory result was obtained and there are practically no adhesions remaining.

Sterility of American Women.—This was the title of a paper presented by Dr. George J. Engelman of Boston and is based on statistics obtained from town records and family histories in various parts of the country. An analysis shows that a century ago the sterility of the American woman was but 2 per cent., the lowest in any civilized country on the globe, while the fecundity, *i.e.*, the number of children to a marriage, was 6. At present the sterility is 20 per cent. and the fecundity but 2 to a marriage. These figures show a much higher percentage of sterility among the wealthy classes. Among college graduates the sterility reaches 33⅓ per cent. and the fecundity but 1.4 to a marriage. The generally accepted sterility at present among civilized nations is 11 per cent. The sterility among foreigners in this country is 13 per cent. The French Canadian shows the highest fecundity of any race, amounting to 9 to a marriage. Miscarriage and divorce are concomitants and causes of sterility. Normally there is 1 miscarriage to every 5½ labors. In the United States there is 1 miscarriage to every 2½ labors, and in Boston 1 to 1 3-10 labors. In Canada there is 1 divorce to 6,300 marriages; in the United States 1 to 185, and in Rhode Island, 1 to 8 $^{2}/_{10}$. From 6 to 10 per cent. of all women miscarry normally; the remainder is criminal abortion. Primary barrenness due to utero-ovarian disease, such as gonorrhea or endometritis does not amount to more than 12 per cent. among Americans. That this increasing sterility is not due to increase in utero-ovarian disease is evident from its rapid increase hand in hand with the great progress of gynecology which we have every reason to believe would reduce the number of childless women to a minimum were sterility referable to tangible causes. Sterility is due to the male in 1 out of 5 barren marriages.

Dr. Duff of Pittsburg said that much blame was due to the editors of the daily press in allowing the insertion in their papers of insinuating advertisements for the production of abortion.

Ectopic Gestation.—This paper was read by Dr. W. H. Wathen of Louisville, Ky. Nearly all forms of ectopic gestation are primarily cases of tubal pregnancy. None are primarily abdominal. There has been only one case of ovarian pregnancy reported before the one presented here. In the treatment the vaginal route is to be preferred (1) for almost all of the early cases, (2) after the sac has ruptured when the blood is confined between the layers of the broad ligament or in the cul-de-sac, (3) in slight extravasation in cases of intra-abdominal rupture. Suprapubic section is advisable in all other cases. When the placenta cannot be removed entirely, the cul-de-sac should be opened from below and the edges of the sac should be sutured in the vagina, thus making it extraperitoneal. Then it may be allowed to slough out.

FOURTH DAY—JUNE 7TH.

Puerperal Eclampsia.—This paper was presented by Dr. T. J. Beattie of Kansas City. In all cases of eclampsia the urine contains micro-organisms, but none thus far described can be considered as specific. Albumin in the urine is a secondary manifestation and is due to the direct action of the poison on the renal epithelieum in an effort at elimination. A certain amount of this poison is present in the blood of all pregnant women. The most significant evidence of impending eclampsia is the finding of less than 1 5-10 per cent. of urea in the urine. Veratrum viride is our most valuable drug in this affection. If we give it in a sufficiently large dose the pulse can be kept low and experience has shown that if the pulse remains low convulsions rarely occur. Ten minims by hypodermic injection should be administered and repeated when necessary.

Dr. C. L. Bonifield of Cincinnati, O., said that veratrum viride is an absolute specific in full-blooded individuals with a full, bounding pulse. From fifteen to sixty minims of Norwood's tincture should be given and repeated every fifteen minutes until the pulse falls below 60. It should be kept below 60 for three or four days. It should never be used in thin, anemic women with a small, thready pulse. Morphine and chloral are the best agents in these patients.

Cæsarian Section for Placenta Previa.—This was the title of a paper by Dr. W. J. Gillette of Toledo, O. As a result of a circular letter sent by the author to 1,000 maternity institutions inquiring into the frequency of placenta previa the following data were obtained: Out of 105,935 deliveries there were 216 of placenta previa or one in every 481 deliveries. Thirty-four mothers died, a mortality of 15 per cent.; 96 children died, a mortality of 34⅓ per cent. In placenta previa centralis the maternal mortality was 22 per cent., with a fetal mortality of 70 per cent. In placenta previa partialis the maternal mortality was 11 per cent., and the fetal mortality 31 per cent. None of the mothers died before the seventh month. One-third of the cases reached full term. Dr. Bernays of St. Louis performed the first successful section for placenta previa in 1893. Nine cases of this operation have been reported since that time. A successful case by the author makes ten in all. Four of these have been successful as regards mother and child. Under proper conditions Cæsarian section for placenta previa should not furnish a fetal mortality greater than 10 per cent. and no maternal mortality. The Porro operation is best fitted for these cases because when the patient is first seen she is usually exsanguinated and in such the uterus does not contract well.

Intra-Uterine Amputations.—Dr. Maher of Oakland, Cal., reported the case of a child in whom at birth the fingers of one hand and the toes of one foot were missing. A few days later a spontaneous amputation of the fingers occurred on the hand of the other side. This was shown to be due to fibrous bands that encircled all of the digits. The author believes that these bands were due to a deposit of fibrin from the amniotic fluid.

Gynecology; Its Contributions to Surgery.—This was the title of a paper by Dr. Henry O. Marcy of Boston. Ovariotomy has advanced with more rapid strides in this country than elsewhere. Dr. Burnham of Lowell, Mass., was the first one who ever performed myomectomy for fibroid tumors of the uterus. The author himself performed the first cholecystotomy ever reported. Gynecology as a specialty is rapidly disappearing. The gynecologist is gradually becoming a specialist in abdominal surgery.

The following officers were elected for the ensuing year: Dr. J. G. Carstens of Detroit, Mich., Chairman; Dr. C. L. Bonifield of Cincinnati, O., Secretary.

BOOK REVIEWS.

THE HISTORY OF MEDICINE IN THE UNITED STATES; A Collection of Facts and Documents Relating to the History of Medical Science in this Country, from the Earliest English Colonization to the Year 1800, with a Supplemental Chapter on the Discovery of Anasthesia. By FRANCIS RANDOLPH PACKARD, M.D. Illustrated. 8vo., pp. 542. J. B. Lippincott Co., Philadelphia and London, 1901.

DR. PACKARD has gathered innumerable incidents from private papers and early journalistic records to bring clearly before the mind of the reader the conditions under which the practice of medicine rose from a combination of rough horse-doctoring and quackery to a science deemed worthy of university standing. He treats in particular of the American colonies, the early medical education and schools, the place of medicine during the War of Independence, and the first attempts at organizing medical societies and medical literature.

Most fascinating is the manner in which Dr. Packard has combined the results of his investigations and the more or less unimportant facts of the early quackery among the colonists, with the familiar events of history. Anecdotes, quotations from diaries and extracts from old letters, and various early prescriptions, form a quaint and realistic setting for the actual statistics; while the detailed accounts of the fevers and epidemics prevalent during the seventeenth century, show with what care all the existing sources of information have been studied in order to clearly set forth the exact position of the New World in regard to the rise and knowledge of medicine.

Great attention is paid to the first efforts to-

ward a proper medical education in this country, showing the change from the simple apprenticeship of the student to some local doctor, to the final establishment of schools of medicine, and a particularly full description is given of the founding of the medical department of the University of Pennsylvania, and the establishment of the first hospitals. The lives and efforts of all the early physicians and surgeons are carefully outlined, with the particular movements with which they were connected.

In treating of the place of medicine and of hospitals in the War of Independence the author has been most successful in giving the atmosphere of the times and portraying the struggles and difficulties of those engaged in caring for the wounded. Even in these times there seem to have been political snags; and though many of the foremost doctors occupied military posts of great importance, they seem to have encountered difficulties in obtaining the needful supplies for their medical duties.

The last chapter of the book must be mentioned especially as differing from the rest of the volume. It gives a most interesting account of the discovery of anesthesia by Dr. Crawford Long in 1842; and the rival claims of Drs. Jackson and Wells; also the manner of first using ether to benumb the senses, and its first application to a private patient of Dr. Long's. The final description is of the first public use of ether at the Massachusetts General Hospital, by Dr. Morton, and the subsequent adoption of this anesthetic throughout the country.

The whole volume is a very skilful combination of the early historical facts of medicine, told in a most readable way, and a vast amount of statistics which cannot fail to be interesting to all concerned in the study of medicine. Many of the statistics are of the beginnings of what are now world-renowned institutions, and to have them so collected from their various almost unobtainable sources and arranged in compact form will be a great satisfaction and pleasure to any desiring to ascertain points of historical importance in the early development of medicine in the United States.

A SYLLABUS OF NEW REMEDIES AND THERAPEUTIC MEASURES; With Chemistry, Physical Appearance and Therapeutic Application. By J. W. WAINWRIGHT, M.D., Member of the American Medical Association, U. S. Pharmacopœial Convention of 1900, American Chemical Society, etc. Chicago: G. P. Engelhard and Company, 1901. Pp. 224.

THAT many of these new remedies are extensively used goes without saying, yet from the scattered or interested literature about them, one has difficulty in reaching conclusions as to their value. So the author's attempt to search this literature, and by abstracts of the material at hand to make a convenient and concise handbook will be appreciated by the practitioner. The author wisely refuses to consider the many patented mixtures that are sold as coal-tar products, but takes up those the chemistry of which is known, or the exact formulæ of which are given. Besides the ordinary list of remedies he has discussed under separate headings anesthesia, animal remedial preparations, the Nauheim treatment, cold and heat and serumtherapy. As is the custom among the best writers, the doses are given in the metric system, being followed, however, in each instance, by the equivalent amounts in Troy measurement. Almost no attention is paid to chemistry, and but little to solubilities and incompatibilities, the book being essentially a therapeutic summary. Like its fellows in the Standard Monograph Series, this book is handsomely printed and bound with uncut edges and gilt top. It will form a creditable addition to one's materia medica library.

BOOKS RECEIVED.

ORIGINAL ARTICLES.

A STUDY OF SIXTEEN HUNDRED AND FIFTY BLOOD EXAMINATIONS FOR THE WIDAL REACTION WITH SPECIAL REFERENCE TO SO-CALLED PARTIAL REACTIONS.[1]

BY ROBERT J. WILSON, M.D.,

OF NEW YORK.

IN presenting this paper for consideration I wish first to direct attention to the fact that the examinations have all been made by one person, and that they have all been restricted to a certain rule, *i.e.*, certain phenomena must be present in every examination to constitute it a reaction, thereby reducing the personal equation to the very lowest degree. In commencing the examination of suspected typhoid bloods I had made for my use a book so ruled as to give a column each for these phenomena: (1) Effect on motility; (2) effect on the integrity of the individual organisms; (3) the amount of dirt and detritus in the hanging drop; (4) the number of bacilli near the edge of the drop; (5) the number, character and location of the clumps; (6) the dilution.

The culture was examined immediately upon being mixed with the suspected blood and to each column in the book was added a note on the conditions ascribed to it.

The examinations were made at frequent intervals, the phenomena being noted each time. It was not until after I had made several hundred examinations that I was struck with the number of bloods showing practically the same phenomena (where there was marked effect on the motility and decided clumping of a peculiar kind), and that I commenced the study of these bloods with the idea of later submitting them for consideration.

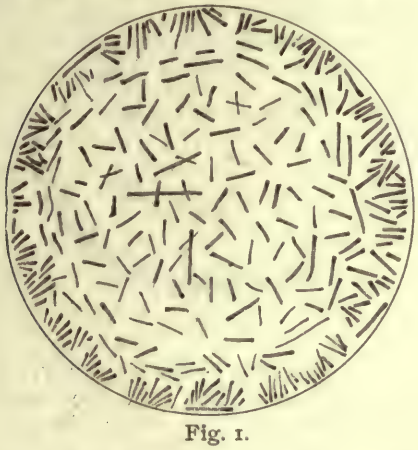

Fig. 1.

To the end that one may thoroughly understand what is meant by the term "Widal reaction" in this paper, I have had drawings made of microscopical fields of the typhoid bacilli in bouillon cultures, both before and after the addition of typhoid blood, and also after the addition of blood from a case of another febrile condition, where there has been a so-called partial reaction.

In making the hanging drop to be examined it is necessary to have it of such depth that it will show at least three focal planes, otherwise the examination will be incomplete and unsatisfactory.

Fig. 1 shows a microscopical field of the top of a hanging drop of a normal bouillon culture of typhoid bacilli. This culture is twenty hours old and the organisms are freely motile. This represents the control drop used for comparison with the drop of the same culture to which has been added a little of the blood of a person suspected to have typhoid fever. Note these points in Fig. 1; the organisms are evenly distributed throughout the field except at the edge of the drop where they are gathered in great numbers; they show great activity here, seemingly trying to crowd to the very edge. This attraction is probably due to the action exerted on the organisms by the oxygen in the air, which naturally exerts positive chemotaxis on all aerobic organisms.

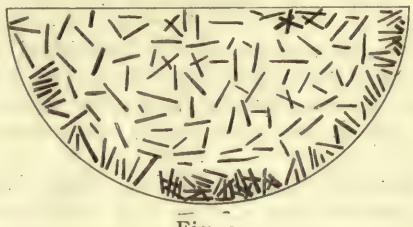

Fig. 2.

Fig. 2 shows a cross section of the drop represented in Fig. 1, and you will notice that the bacilli are evenly distributed throughout the drop, except at one place in the focal plane *a* and again in the focal plane *c*. It sometimes happens that there is something adhering to a supposedly clean cover-glass which attracts the bacilli to that point where they appear as fairly well defined clumps, more or less like the true clumps due to the agglutinating substance in typhoid blood. The increase in organisms at the bottom of the drop in the focal plane *c* is easily accounted for by the fact that gravity naturally carries the dead and non-motile organisms to the bottom, these frequently assuming the character of clumps.

If you can find a field in any focal plane of the hanging drop free from clumps, you can be quite sure that any clumping present is not due to any

[1] Read before the Society of Alumni of Bellevue Hospital.

agglutinating substance which necessarily will affect organisms in every focal plane.

Fig. 3 shows the microscopal appearance of the top of a drop where the Widal reaction is present. Notice first that the organisms have been drawn together in groups and that the individuals of each group appear to be loosely held together. Viewed under the microscope these clumps are practically quiescent there being very

Fig. 3.

little movement, either of the individual organisms or of the clump as a whole. The edge of the drop is practically free from organisms, showing that the air no longer exerts any influence on them.

Fig. 4 shows a cross section of the hanging drop shown in Fig. 3; you will notice that the clumps are evenly distributed throughout the drop, with perhaps some increase in the numbers and compactness of the clumps at the bottom.

Fig. 5 shows the microscopal appearance of the

Fig. 4.

top of a hanging drop of a bouillon culture to which has been added some blood of a patient suffering from a febrile condition not caused by typhoid infection, but which exerts a marked influence on the typhoid organisms. You will notice that there are many organisms at the edge of the drop. The air exerts the same influence on the bacilli that it did before the addition of the blood. Note the character of the clumps, generally compact at the center with the bacilli at the edge of the clump usually attached by one end only.

Very frequently these clumps have the appearance of being built up around a piece of detritus present in the drop. All the organisms comprising the clump seem to have retained part, at least, of their motility, those on the edges being particularly motile so far as their free ends are concerned. When motility is very much inhibited, these clumps have a peculiar trembling movement, which is like the molecular movement described as Brownian.

Fig. 6 shows a cross section of the drop represented in Fig. 5; note the same character of the clumps in every focal plane. The large number of motile bacilli and the number attracted to the edge of the drop by the air. The appearance of the drop shown in Figs. 3 and 4 is what has been taken to constitute a Widal reaction in this study and when any of the characters there shown have been absent, the blood has been classed as not giving it.

Fig. 5.

In this study I have had access to the records of all the Hospital cases, and have carefully looked over the history of every one. In the cases in private practice, those giving a partial reaction only have been studied; 1,003 of the cases occurred in hospitals and 647 occurred in private practice. The 117 cases referred to later in this paper which had typhoid fever and in which no reaction occurred were all hospital cases. It is probable that a proportional number occurred in the cases in private practice.

These blood examinations have all been made in the Department of Health Research Labora-

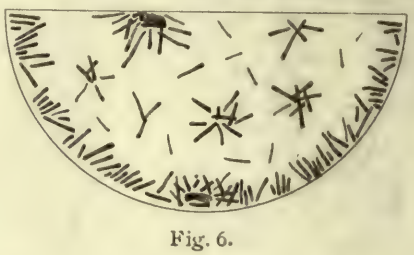

Fig. 6.

tory and they represent blood from a great variety of cases, where at the time the blood was sent to the laboratory there existed in the mind of the medical attendant a doubt as to what the disease might prove to be. Naturally most of them were sent comparatively early in the disease, so that failure to get reactions in the typhoid cases is not to be wondered at.

The blood of a patient in most instances was

sent only once, I suppose either because the symptoms were so pronounced that it was not thought necessary to have the blood again examined, or the case proved to be typhoid. This was unfortunate so far as laboratory results were concerned, for it leaves our work but half completed. If the physician would only looked past his own immediate interest to that of the profession at large such studies as this one could be made of far greater value because they would show the complete statistics. Most of these cases, so far as I can ascertain, were only suspicious of typhoid at the time the blood was sent and this reason, combined with the early day in the disease where typhoid infection did exist, accounts for the comparatively few Widal reactions.

Of the bloods examined 265 gave the Widal reaction. Forty-six were sent on or before the seventh day of the disease; 36 from the eighth to the tenth inclusive; 50 from the eleventh to the fourteenth day inclusive; 28 from the fifteenth to the twenty-first day inclusive; 7 from the twenty-second to the twenty-eighth day inclusive; 5 from the twenty-ninth to the thirty-eight day inclusive and in 93 the day of disease was not mentioned. In 34 cases the Widal reaction occurred upon the second examination of the blood, of these, 2 were negative on the third day and positive on the eighth and tenth days respectively; one negative on the fifth day and positive on the thirteenth day; one was negative on the sixth day and positive on the ninth day; 8 were negative on the seventh day and positive on the eighth, ninth, tenth, thirteenth (2), fifteenth (2), and seventeenth days respectively. One was negative on the eighth and positive on eleventh day. One was negative on the ninth and positive on the sixteenth day. Five were negative on the tenth and positive on the eleventh, twelfth, thirteenth, fourteenth and twenty-fourth days respectively. One was negative on the eleventh and positive on the fifteenth day. Two were negative on the twelfth and positive on the fourteenth and twenty-sixth days respectively. Five were negative on the fourteenth day and positive on the sixteenth (2), seventeenth, nineteenth and thirty-third days respectively. One was negative on the sixteenth and positive on the twenty-first day. Two were negative on the twenty-eighth day and positive on the thirty-fourth and thirty-eighth days respectively. One was negative on the thirtieth day and positive on the thirty-second day. One was negative on the thirty-fifth day and positive on the thirty-seventh day.

In three cases the day of the disease on which the blood was first examined could not be ascertained. They gave the reaction on the twenty-sixth, sixty-fourth and eighty-fourth days respectively. In all of these late cases it is probable that the reaction would have been noted earlier had the blood been sent at frequent intervals after the first examination.

The Widal reaction was found in 8 cases that were not diagnosed typhoid and which gave no history of a previous typhoid infection. Three were malaria; of these, two were soldiers from a typhoid-infected camp and one had had a continued fever two years before. One was a case of diarrhea, no other diagnosis; this case was discharged improved after having been in the hospital nine days, this also was a soldier from a camp where typhoid infection was common. One was a case of puerperal fever complicated with phthisis. At the autopsy of this case tuberculous ulcers were found in the small intestine. There was one case of cerebral hemorrhage where there was no history and no autopsy. There was one case of chronic endocarditis and one case of splenic infarction with rupture.

I think that all of these eight cases speak pretty well for themselves, without my making any comment upon them further than to say that the possibility for error of diagnosis in all such cases is very great. There were 1,115 bloods examined that did not react at all, of these 117 proved to be typhoid. The blood was only sent to the laboratory one time. Forty-one specimens of blood were sent from the fourth to the seventh day of the disease, inclusive—fourth, 12; fifth, 13; sixth, 4; seventh, 12; 22 from the eighth to the tenth day, inclusive—eighth, 18; ninth, 8; tenth, 6; 23 from the eleventh to the fifteenth day, inclusive—eleventh, 14; twelfth, 2; fourteenth, 2; fifteenth, 5; 18 from the sixteenth to the twenty-first day, inclusive—sixteenth, 6; seventeenth, 2; eighteenth, 1; nineteenth, 2; twentieth, 3; twenty-first, 4; 3 from the twenty-second to the thirty-seventh day, inclusive—thirtieth, 2; thirty-seventh (1), and there were ten that were not dated, so the day of disease could not be found. Of the typhoid cases where blood was sent for examination only once and no reaction obtained, 35 per cent. were sent before the end of the seventh day of disease; 38 per cent. after the seventh day and before the end of the fifteenth day of disease, and 27 per cent. after the fifteenth day of the disease, all but three of these being sent during the third week of illness.

There were 160 cases that did not give a typical reaction, but that did give a partial reaction to such a marked extent as to lead me to believe that these reactions might possibly be due to the agglutinating substance of typhoid. The clumps, while differing from those that are found in a Widal reaction, were present in every field and were well defined, but the fact that they were usually made up of more or less motile organisms, and that the edge of the drop was never free from organisms, caused them to be classed as not Widal reactions.

I have analyzed these cases as carefully as possible where access could be had to the records of them and find that they naturally fall into two classes, those occurring in hospitals and those occurring in private practice. There were 37 cases that occurred in private practice, of these 20 were called typhoid and were divided as follows: One walking case, 2 mild cases, 1 abortive case, 15 ordinary cases, and 1 protracted case.

Thirteen cases were not typhoid, divided as follows: 3 where no diagnosis was made, 3 intermittent fever, 1 fecal impaction, 1 la grippe, 1 colitis, 1 acute indigestion, and 1 enteritis. In four instances no response was received to the letter of inquiry sent out.

Of the 123 hospital cases there were 56 where no records were kept of the cases, but from the fact that the histories of typhoid-fever cases have been apparently well kept in all the hospitals visited, I think that it is safe to assume that most, if not all of these 56 were not typhoid. Of the remaining 67 cases where records were kept, 8 were typhoid fever, 15 were not diagnosed, 10 were tuberculosis, 16 were malaria, 4 were bronchitis, 4 pneumonia, 1 pleurisy with effusion, 1 nephritis, 2 anemia, 1 pericarditis, 1 gonorrhea and 1 submersion.

In private practice 54 per cent. of the partial reactions occurred in typhoid infections while in hospitals 6.5 per cent. only occurred in typhoid infections. It seems to me that it is not improbable that some of the cases in private practice were continued fevers other than typhoid.

I shall base my conclusions, so far as the partial reactions are concerned, on the hospital cases where fairly-accurate histories were kept. No attempt has been made in this study to find out how often the Widal reaction occurs in typhoid fever; that point has been pretty well determined and it is generally conceded, I think, to be about 95 per cent. of all cases. Had all the physicians sending blood to the Health Department Laboratory been as much interested in the scientific side of the investigation as they were in the clinical, our statistics would be much more valuable.

In this study, of those giving positive reactions 33 per cent. occurred in the first week; 84 per cent. before the end of the second week; 16 per cent. in the third week and 4 per cent. in the fourth week. The fact that so large a percentage occurred as early in the disease as the second week would tend to show that the examination of the blood, so far as these cases were concerned, has been of material value to the physician in charge. Where the reaction occurred upon the second examination of the blood, 56 per cent. were found before the end of the second week; it is highly probable that this percentage would have been much larger had another specimen of blood been sent back promptly upon receipt of the result of the laboratory examination of the first specimen. Of the typhoid bloods where no reaction was obtained all but 27 per cent. were sent before the sixteenth day of the disease, and there is no reason to believe that the reactions would have been absent had second specimens been sent for examination during the second and third weeks. Less than 7 per cent. of the partial reactions were found in typhoid infections in the hospital cases. These partial reactions occurred with greater frequency in both tuberculosis and malaria than they did in typhoid. They were found in thirteen different conditions, and I have no doubt that, if blood was sent from a general medical ward and from febrile cases, this list would be greatly augmented.

The value of the partial reaction to the clinician is absolutely *nil*, I think, except in so far as it has occurred in a few typhoid cases it would be an indication to send another specimen of blood for examination. In the bloods where the Widal reaction occurred on the second examination there were only two where the partial reaction was present on the first examination. There is no reason to believe that this partial reaction would have not been present had the patient been suffering from any of the diseases enumerated above, instead of a typhoid infection.

In summing up the results of this study, it seems to me that they can be embraced in these two sentences: First, that these cases where the Widal reaction has been present are only further evidences of the already-known practical value of the reaction. Second, that the so-called partial reactions are valueless so far as the clinician is concerned.

A NEW METHOD OF DETERMINING APPROXIMATELY THE AMOUNT OF HYDROCHLORIC ACID IN THE GASTRIC CONTENTS.*

BY MAX EINHORN, M.D.,

OF NEW YORK;

PROFESSOR OF MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

THE usual method of titrating with phenolphthalein and one-tenth normal sodium hydrate solution for determining the total acidity, and with Toepfer's solution for the free HCl, requires a certain amount of stomach-contents (about 10 cc.). When we have to deal, however, with very small quantities neither of these two methods is practicable. The amount of contents obtained by the examination with the stomach-bucket is always so small that we cannot very well filter and titrate it.

It was Günzburg[1] who first tried to estimate approximately the quantity of HCl by another method than titration. For this purpose he made use of his well-known phloroglucin-vanillin reaction, determining how many times the stomach-contents could be diluted with water before the reaction disappeared. Until recently I always employed this method in cases in which there was only a small amount of gastric contents at hand. Günzburg's test, namely, evaporating a drop of gastric contents mixed with a drop of Günzburg's reagent in a porcelain dish over a spirit-lamp, is somewhat complicated and lengthy, particularly as the same procedure must be repeated after each dilution.

I have lately made use of a somewhat more simple method which in exactness I believe to be equal to that of Günzburg. For this purpose I employ the solution of dimethylamido-azo-benzol recommended by Toepfer. I do

* Read before the German Medical Society of New York.

[1] Günzburg. Centralblatt f. klin. Med., 1887, No. 40.

not, however, make use of the solution directly, but of filter paper, saturated with it[2] (similar to Congo paper).

The procedure is as follows: A minute quantity of stomach-contents is placed by means of a glass rod upon a strip of dimethylamido-azo-benzol paper (one-half by eight centimeters). If the paper turns red one drop of the contents is diluted with two drops of water in a small porcelain dish. A glass rod is dipped into the mixture and the test paper again touched. If it still turns red, one or two more drops of water are added and the procedure repeated as before. This is done until only a slightly red or almost no red color is produced by the mixture upon the test paper. In this way the amount of dilution required for a trace reaction with the test paper is determined. It is clear that the more HCl there is in the stomach-contents the more they can be diluted, still giving a trace reaction with the dimethyl-amido-azo-benzol paper.

In order to determine the clinical value of this method I have examined the gastric contents of 21 patients (about one to one and one-half hours after a test breakfast) according to the usual titration method and also by means of dilution and testing with the dimethylamido-azo-benzol paper. The results are given in the accompanying table.

TABLE COMPARING THE DETERMINATION OF HYDROCHLORIC ACID IN STOMACH-CONTENTS BY MEANS OF THE USUAL TITRATION METHOD AND BY MEANS OF DILUTION AND TESTING WITH DIMETHYLAMIDO-AZO-BENZOL PAPER.

No.	Name	Date	Titration Methods		Dilution and Paper Method
			Total acidity	Free HCl

17	H. P. H.	4, 4, '01	92	74	6+, 8 tr.
18	H. K.	5, 7, '01	96	80	5+. 9+, 14 tr.
19	J. N.	3, 20, '01	96	76	4+st., 8+, 12 tr.
20	J. A. W.	5, 9, '01	100	80	5+, 8 tr.
21	S.	3, 2, '01	100	80	8+st., 12 tr.

Before considering the table, I would like to remark that I have excluded from this comparative investigation all cases in which the addition of dimethylamido-azo-benzol to the stomach-contents did not produce a red color, as the absence of free HCl is self-evident in these cases.

Looking at the table we see that in Cases I.-VIII., in which the total acidity varies between 36-68, the amount of dilution, necessary to obtain the end reaction with the dimethyl-amido-azo-benzol paper oscillated between 3-6, the larger numbers usually corresponding to a greater acidity. Only once (Case VI.) did we meet with an exception; here the acidity was 60 and the amount of dilution 12.

In the second group, Cases IX.-XXI., all suffering from hyperchlorhydria, the acidity varied between 72-100 and the amount of dilution between 7-18. Usually the higher amounts of dilution corresponded to a greater acidity, only once with an acidity of 100 the amount of dilution was 8.

Summarizing the results of the table, it is fair to assert that in a majority of cases there exists a certain relation between the acidity and the amount of dilution necessary to produce the end or trace reaction with the dimethylamido-azo-benzol paper. A dilution of from 3-6 would correspond to a normal, under 3 to a subnormal acidity, and over 6 to hyperacidity.

The numbers given refer to the examination one to one and one-half hours after Ewald's test breakfast. If we have to test after other more complicated meals (test dinner, etc.) hyperacidity would be indicated by somewhat smaller amounts of dilution (from about 6 times on), since we estimate approximately only the free HCl and the amount of the latter is relatively small after meals containing much albumin.

The method just described of approximately determining the quantity of free HCl in the stomach-contents will be of value in the following two conditions: (1) In examinations with the stomach-bucket, or where from other causes only small quantities of gastric contents are at our disposal. (2) In cases in which it is of importance to obtain at once an idea regarding the amount of acidity and the necessary solutions for titration are not at hand.

[2] The dimethylamido-azo-benzol paper can be obtained from Eimer & Amend, 18th street and Third avenue, New York.

LOCAL TREATMENT OF FEMALE DISEASES; ITS ABUSES.[1]

BY A. L. BEAHAN, M.D.,
OF CANANDAIGUA, N. Y.

THE advance in all branches of medical and surgical art requires frequent shifting of means and technic. The discussion of the local treatment of female diseases needs to be rewritten. A brief consideration of a few features that are easily demonstrable will be of probable interest.

The appreciation of diseased conditions is best obtained when all the senses required are brought to bear. To see and to feel leave but little doubt and the interpretation of the meaning of discoveries becomes easy.

To abdominal operations we are indebted for correction of our views of pelvic pathology and to new views of rational therapeutics and treat-

[1] Read before the Rochester Academy of Medicine.

ment. Such terms as peri-uterine cellulitis, pelvic peritonitis, pelvic abscess, pelvic hematocele, pelvic cellulitis, perimetritis, parametritis, metritis, endometritis, cervicitis, endocervicitis, ulceration of the cervix, menorrhagia, and metrorrhagia, need to be reviewed and modified or abandoned.

Much has been done in this direction, but many vagaries remain in minds permeated with the methods of quite recent times, and a strong impress has been left on the thought and practice of gynecology.

The commercial spirit has developed. Mechanical devices increase, the large sales of chairs and tables have invited undue emphasis to their uses. Applicators of all form abound. Drug houses add surgical specialties and present the new and great sellers to the profession they canvass with much profusion and persistence. The recent innovation of a gauze packer has been especially commended. Gauze packing is, with few exceptions, non-surgical, for it obstructs drainage and invites sinuses. To introduce the body tube into the uterine cavity, a preliminary dilation of cervix would usually be required. The sharp edge of the end of tube and its size are enough to condemn it; but its large sale is evidence that the trend of our practice is wrong. A small electric-lamp is vaunted as useful in vaginal exploration. The eye, with sunlight, and the finger, with educated touch, are simple and less cumbersome. The various forms of Peaslee needles are hawked around, regardless of the fact that Emmet long ago taught the classical principle that the perineum should be sewed from within and elevated, rather than sewed from without and depressed. Uterine applicators are fair sellers, but the profession must appreciate that they are harmful, even dangerous.

The subject of abuses may properly be studied best not from the standpoint of the instruments and appliances alone, but from the diseases to be met and the remedies to be used in their relief.

The most dangerous procedures are perhaps intra-uterine examinations, operations and applications. It is easy in the virgin to find an os uteri with a pin-hole opening, a tenacious plug, a superficial erosion. It is too readily appreciated in primiparæ or multiparæ that the os uteri is ulcerated, the uterus subinvoluted, its mucosa soft and studded with granulations. It requires a steady breadth of conception not to fall into the error of finding too much or exaggerating trivial symptoms into symptoms complex. The most dangerous instruments used in treating these diseases are dilator, sound and curette. The dilator of common use, Goodell's, has in the hands of the writer in at least two instances torn its way into the pelvic cavity. The second time was only a few days subsequent to the first, and great care was being exercised, but in the subsequent curetting of each case this instrument passed suddenly into the pelvis. I am sure this happens oftener than appreciated, especially in women who have never been pregnant. The sound should never be used. Its usefulness is more than offset by its dangers, both as to mechanical and germ-carrying features. The curette is of use when the uterus has failed to expel part or the whole of the products of conception, or when later the uterus does not contract because of fungous granulations of the membrane of uterine cavity. But the curette should be used with great circumspection and after careful eliminating diagnosis. Its use should rank with major operations and similar careful preparation should be made for its performance. Large, smooth, loop curettes should be employed to remove placental debris.

It has been my misfortune to remove on several occasions ovarian cysts filled with old blood extravasations subsequent to curettement. It seems probable that the violence to the uterine mucosa may have caused the pelvic congestion and effusion of blood into cysts. I have not met with these blood signs except when curettage had preceded the ovariotomy. In these cases temporary relief was afforded an associated dysmenorrhea, but in a few months the monthly pains were anguish in one patient and severe collapse, with hysterical delirium, imperceptible pulse, pallor and cold extremities were present. The curette is a valuable aid, but it needs to be used with more judgment than perhaps any other gynecological instrument.

The so-called local application for female diseases opens a number of chapters of interest. The patients recite with their friends the number they have received. The physician expects two or three visits a week, and for what? Does an erosion, the everted lips of a laceration, the tenacious mucus within the os, the thin, watery discharge from the uterine cavity, the enlarged uterus, the swollen appendages, improve by local means as usually applied with applicators from bottles labeled, "solution of nitrate of silver" "tincture of iodine," "carbolic acid," or their similars? How many men of twenty-five years' practice have faith in this work? Is any cause removed? Can a lacerated cervix, an enlarged ovary, a swollen tube, be influenced by cervix applications?

How can tubal disease be relieved when the first portion of the tube is so small and when salpingitis forms strictures, often permanent, so early? How can the uterine mucous membrane, so parchment-like in nature, require the strongest caustics to influence its healing, if diseased?

The use of pessaries has been much abused. They are of some value, but how many cures do they effect? Our instrument drawers are filled with obsolete patterns that attest youthful hopes not realized. Electricity as usually applied seems futile. Its advocates should not overlook the fact that ameliorism of symptoms is not proof of curing disease and careful, not severe, applications should be made tentatively, especially when puncture applications are made, as inflammation, even sepsis, may be caused.

The principles of practice must recognize the causes involved in producing female diseases. Constipation, with full bowel and rectum; the history of the girl at twelve who later applies

for relief from harm that befel her during the critical period of adolescence; the story of confinements not normal and repairs not made in season, with resulting torn and everted cervix or laceration of perineum, with descensus of all the abdominal contents, even the kidneys; the deduction by history or surmise of sexual infections and their sure involvement of the general system, as in syphilis, or the no-less-certain and life-time damage to ovary or tube if exposed to one who has, or ever has had, gonorrhea—all these make a picture that must fasten itself on the thought to make it broad enough to comprehend how female diseases are not to be abused in their treatment.

Calomel and salines indirectly lessen pelvic engorgement by partial depletion and drainage and directly by unloading the rectum and bowel and relieving pressure. Hot-water douches in recumbent posture, followed by soothing alkaline or stimulating astringent solutions of moderate strength, are useful, except in tubal and ovarian diseases, but if pain occurs when they are administered it is proof of harmfulness.

Repair the torn cervix by the Emmet method. Repair perineal laceration by the American or Emmet method of elevating the perineum and anchoring it well up. Remove appendages, if diseased; perform curettement only according to the dictum of this article, and dilate the cervix when demanded. These are general rules which I believe need emphasis.

Local treatment, as applied, will seldom be required. The use of tampons of cotton or wool with glycerine are valuable, but should only be used when the patient is confined in bed. Great care is to be exercised in this procedure, for lives have been lost by peritonitis after elevation of an adherent uterus or appendage has been accomplished by packing. No tampons with any medicament ever incorporated can cure organic tubal or ovarian disease, and their employment may be, as stated, dangerous to life.

As will be seen, the simple treatment of a symptom is out of place when treating female diseases. It is a complex subject and needs to be considered and met in a broad and comprehensive manner that permits neither fads nor methods of abuse.

A medical friend recently called my attention to an evil resulting from indiscriminate "local treatment," which seems probable. That is, the tendency on the part of both physician and patient to overstep the local application with the uterine applicator, and use a similar instrument to induce abortion. Undue familiarity with this form of treatment may invite more than is at first thought anticipated and eventually lead to crime.

This brings to our attention the moral question which is pertinent: Should woman, on whose virtue depends the welfare of a race, be needlessly exposed at frequent intervals to indignities that may foster a spirit of undue liberty and lessen the reserve given her by all the finest attributes of her peculiar organism? "The man who lays his hand on woman save in the way of kindness, is a villain" may be remembered and emphasized with profit by the physician to whom life and honor, remote and present, are both entrusted. The treatment of the sexual organs has always been the field of the charlatan and impostor. In no other form of disease, real or supposed, is it so easy to prey upon the imagination. Let not the power, the marshalled forces, the potent influence of gynecological thought and practice, or of medical work in the broad sense, lend itself to a purpose whose debasement by these alluring frauds indicates the ease with which deception and sham may be wrought where Nature is so strong and yet so weak! The purely scientific principles of practice should be closely followed. The patient's condition after careful diagnosis is to be announced with no evasion, but no fulsomeness, and the remedy, whether radical or systemic, prescribed according to the needs.

The individual is to be swerved from believing herself sick by giving her an increase of courage, stability of will, and a renewed self-confidence. Stimulation of the mind, not depressing statements, sufficient treatment, but not excessive care, will tide over the case and support the mental equipoise.

Mistakes in diagnosis are possible. Within the past thirty-six hours we removed the appendix from a girl of twenty, who had suffered severe menstrual pains for four years. We found the right rectus hard and a temperature of 99.2° to 100.2° F. continuing for two weeks. No appendiceal storm had broken, but at the recurrence of the menses the same fever was present, accompanied by inability to lie comfortably on left side, because of a pulling from the right side, a painful point over appendix, a small but hard appendix and anterior thigh pains. After close observation of the patient for two months the removal of the appendix disclosed its base retracted into the head of the cecum, with a stercolith in the apex of the appendix and the blood-vessels at the head of the cecum enormously enlarged. Probably typhilitis had been present. Passing the finger into the pelvis the right ovary was found to be normal in every way.

The close study of many female diseases will certainly limit the range of usefulness of "treatments," but enlarge the sphere of surgical relief and improve the care of remote and general disturbances.

DISINFECTION WITHIN AND WITHOUT THE BODY IN DIPHTHERIA.

BY M. A. VEEDER, M.D.,
OF LYONS, NEW YORK.

THE effectual control of diphtheria in an individual or a community is a problem that is exceedingly complex. There are at least three forms of disease that have been confounded under the name of diphtheria, and it is only since bacteriological methods of study have come into

use that these have been distinguished from each other with precision, they formerly having been regarded as modifications of the same disease rather than as separate diseases. They are diphtheroid, sore throat characterized by the presence of staphylococci; true diphtheria, characterized by the presence of the Klebs-Loeffler bacillus and septicemic sore throat, characterized as a rule by the presence of streptococci. Although these diseases occur separately they are nevertheless often associated in a characteristic way. Diphtheroid sore throat predisposes to the onset of diphtheria, so that if a patient having the former is exposed to the infection of the latter, diphtheria may begin at once without an incubation period. In like manner either diphtheroid or diphtheria may prepare the way for septicemic sore throat. Indeed, it is doubtful whether streptococcus infection can establish itself in the throat at all without some pre-existing disease, or lesion of the parts, just as erysipelas starts from some small scratch or puncture. Thus the septicemic form of sore throat, although very fatal, is not very contagious.

Diphtheroid is a harmless affection except as it predisposes to diphtheria, or septicemic sore throat, or both. Diphtheria in and of itself is dangerous, but is most dangerous if it becomes the channel through which septicemic infection gains access to the body. Against the streptococcus infection antitoxin is powerless, but the antistreptococcus serum may be used with good effect.

It is a peculiarity of the streptococcus to locate itself in the exceedingly tough and foul-smelling membrane that is characteristic of these cases. Hence the application of strong disinfectant remedies, as, for example, pure carbolic acid, has appeared to be of service. This is a measure, however, not to be recommended in ordinary diphtheria.

Erysipelas, puerperal fever, and septicemic sore throat, all are forms of streptococcus infection closely related to each other. Indeed, any of these diseases may originate the other, the liability so to do depending on the location of the infection in or on parts of the body accessible to the touch, rather than upon differences in the nature of the infection itself. A physician attending such cases should apply the principles of surgical cleanliness accurately and completely for his own security and for that of his patients. It may become necessary to go so far even as to abstain from seeing cases of ordinary diphtheria lest they become septicemic through contact of the physician in attendance with erysipelas, puerperal fever, or septicemic sore throat. During epidemic prevalence of diphtheria, the occurrence of diseases of either of these classes may have special significance and should be carefully watched with a full understanding of the dangers involved.

Furthermore, every surgeon knows that the danger of septicemia is very much increased if operations are undertaken in buildings where the plumbing is bad, and where there are untrapped drains. It is true that antiseptic dressings decrease the risk somewhat even under the most unfavorable surroundings, but a sore throat cannot be protected every hour and minute, as is a wound, and if that throat is diphtheritic, the barriers against septicemic infection are as absolutely down as though there were an open wound. The traditional prejudice against foul drains and the like as a source of specially malignant diphtheria is not without warrant. Indeed, such receptacles and not the throat itself appear to be the natural habitat of infection of this class. If carried on the person, it is by accident rather than as a part of the usual life history of the streptococcus infection.

The Klebs-Loeffler bacillus, on the other hand, appears to find its natural habitat in the throat, it becoming more or less atypical when grown in culture media outside the body. Although irregular in form and having its presence masked by that of other micro-organisms, there is nothing to prevent its growth in the albuminous material crusting the interior of drain pipes that are never cleaned nor flushed, unless it be too low a temperature at times. But the dried sputum from a diphtheritic patient kept at ordinary temperature has been found capable of originating living colonies of the bacillus for six months. This being the fact, the Klebs-Loeffler bacillus certainly could remain alive perhaps from year to year in underground drains, although leading a fluctuating and precarious existence. Such receptacles are specially liable to contamination through rinsings or expectorations from the mouths of persons having diphtheria, and thus also the infection may be renewed and kept alive, the persons living on the premises originating their own antitoxins and becoming immune. Where this has happened quarantine and antitoxin no matter how carefully applied with the aid of bacteriological tests, fail to eradicate the disease completely. The writer has met with instances which appear to be beautiful illustrations of this in three or four large institutions.

In an emergency of this sort where it is not possible to wait for improvement of drain pipes and plumbing, it is well to know that such fixtures, when incapable of being flushed adequately, can be sterilized by the aid of chlorine gas. In the presence of septicemic sore throat especially, this resource may be of the highest importance.

Nor is the diphtheroid form of sore throat unimportant. This form of throat trouble is much more common at all times than is generally supposed, not attracting attention, recovery being so rapid, unless the more serious diseases of the throat become prevalent, whereupon numerous cases of this type are brought to the attention of the physician, and are commonly classed as diphtheria for reasons that will appear shortly.

As has already been intimated diphtheroid predisposes both to diphtheria and to septicemic sore throat, shortening the incubation period to such an extent that the bacteriological test may show the throat clear from diphtheria one day and

strongly infected the next. There being such increased susceptibility a diphtheroid case may readily become diphtheria in the very act of examination unless adequate precautions are taken.

The fact that the physician's own throat is not red or sore is no proof that it is not infected, for infection often occurs without symptoms, particularly in adults when strongly exposed, and there is no stronger exposure than to receive the spray that comes from the mouth and nostrils of a child that is coughing and crying, as they often do, during an ordinary examination of the throat. The writer has met with very conclusive evidence that such particles of spray floating in the air are able to carry the Klebs-Loffler bacillus a distance of several yards. If the physician thus infected during an examination goes to another case without proper precautions, even though it be at an interval of several days, his own breath, and the spray from his lips in the act of talking, if nothing more, may convert a case of harmless diphtheroid into severe diphtheria in an hour.

This is the danger also that militates against the use of the bacteriological test to determine whether quarantine shall be established or not. Such testing can be relied on at the outset of quarantine only when it can be known with certainty that there is no secondary source of infection such as that just described. In other words, unless physicians in attendance upon cases of diphtheria, or moving about in a community where diphtheria is epidemic, have their own throats tested to see whether they themselves are clear of infection, and especially whether any precautions they may take are adequate, it is better to regard all cases of diphtheroid as diphtheria provisionally, using the bacteriological examination mainly for the removal of quarantine rather than for its establishment. If these suggestions are followed out thoroughly, there may be a surprise awaiting not a few members of the profession. The very anxiety that leads to seeing cases frequently, and testing and examining them often, may be a means of spreading the disease. The routine that the writer has been led to adopt is to be provided with squares of antiseptic gauze and corrosive sublimate tablets. A square of such gauze may readily be held over the mouth and nostrils with the left hand while the right hand is free to use the tongue depressor or swab. Both hands and the face should be wet with the sublimate solution before and after the examination and the gauze may be burned after being used. This, together with frequent spraying and cleansing of the mouth, throat and nostrils, and bacteriological testing, affords very complete security against either giving or receiving infection.

There are many precautions that will readily suggest themselves in regard to the care and disinfection of articles that have touched the mouth or lips on which infection may remain for extended periods in the form of dried saliva. Perhaps the worst of all such articles is the ordinary lead pencil, the use of which should be absolutely forbidden every diphtheria patient. The infection of milk through the agency of some one having a diphtheritic throat coughing or sneezing while handling it seems to have occurred in a case or two that have come to the knowledge of the writer. Sterilization of milk by boiling is the proper method during diphtheria epidemics, and always.

As regards ridding the mouth and throat of infection, there are a few points that deserve more extended notice than can be given them on this occasion. Especially important is the behavior of the diphtheria bacillus where there are cavities in the teeth. In such cases the person thus infected becomes immune, as if from antitoxin, but there is frequent recrudence of sore-throat trouble more or less typical in its resemblance to ordinary diphtheria. Often there are red spots somewhere near the bad tooth, or exactly opposite it on the interior of the cheek. These come and go, and there may be evanescent traces of membrane on the tonsils at intervals of weeks and months. Bacteriological examination at times shows the presence of the bacillus, and at times its absence. Sometimes it can be found by inserting a swab into the tooth cavity when not apparent in the mouth. A very interesting case of this sort under my observation after an exceedingly prolonged quarantine infected another person through the intermediary of a lead pencil, showing that although the bacillus had been present and absent in a curious way, and the throat symptoms had varied fitfully, there was true diphtheria infection throughout a period of at least four months. In this case there was a deep cavity concealed between two teeth and recovery was not perfect until the tooth itself had been removed.

In these cases the bacillus appears to be nourished by fresh supplies of particles of food, such as meat and potato, lodging in a cavity as in a culture tube at each meal. Thus the process is perennial and infection does not die out as it does when the throat alone is infected. It would seem that sterilization of the tooth cavity by cauterization would reach the source of the trouble at once, but it does not, the few bacilli remaining elsewhere in the mouth apparently reinfecting the cavity. A better plan is to insert a pledget of cotton saturated with some disinfectant solution before and after meals. Even then in very bad cases it may be well to have the tooth extracted.

An observation of this sort is very suggestive as to the amount of care required to be of any material service in ridding the mouth and throat of diphtheria infection by methods of disinfection. The perfunctory use of sprays, swabs or gargles apparently accomplishes so little in shortening the period of quarantine that some physicians practically have come to rely on giving the antitoxin and waiting. But where the infection is harbored and kept alive in the manner that has just been described neither the antitoxin nor waiting will insure recovery within any reasonable length of time. Meanwhile the person may have infected unconsciously a whole neighborhood or town.

Very likely the bacillus when lodged in the

spongy portions of the tonsils, or in some fold behind the palate, or in the nostrils, will die out gradually as the person becomes immune. But the process of its removal may be hastened and made more secure by constant sterilization of the parts as far as possible. Remedies for the purpose should not be irritating, in order that they may be employed constantly at very frequent intervals, the growth of the bacillus and its diffusion through the mouth being very rapid. Peroxide of hydrogen made alkaline by lime-water, or by the addition of equal parts of Dobell's solution is very good. Freshly made chlorine water with the addition of a little tincture of iron is highly efficient. A soft camel's hair toothbrush kept in a two-per-cent. solution of carbolic acid, and used with a lather of Castile soap is of great service, as is also dental floss drawn between the teeth. Such measures persisted in will clear up, as a rule the most refractory case, as determined by bacteriological examination in about a month, very few cases showing perfectly clear in as short a time as three weeks.

It has been the purpose of the present discussion to outline a few leading features so that whatever measures of disinfection are adopted, whether within or without the body, they may be used with full knowledge of the dangers and difficulty and complexity of the subject of control of diphtheria.

CEREBRAL APOPLEXY: ITS RELATION TO TESTAMENTARY CAPACITY.[1]

BY CHARLES SCHRAM, A.M., M.D.,
OF NEW YORK.

IN offering a paper of this character to the Society, I am aware that it is in the nature of an innovation, being of necessity of a less scientific type than has marked those heretofore read. Yet its importance is manifest. It is the duty of every member of the profession to elevate and dignify the position of the expert, because through him the profession is exhibited to the public eye in a glaring light. By assisting him to speak with confidence on subjects whereon his opinion must be sought by the State, this duty is best subserved.

Apoplexy occurs at an age when individual responsibilities are apt to be greatest. Its victims are usually within the decade between the forty-fifth and fifty-fifth year. They have had time and opportunities for the accumulation of wealth and the attainment of posts of importance and prominence. The keen struggle for self-advancement and indulgence in the luxuries wealth affords seems to have caused a rapid increase in the number of apoplectic seizures. According to Dercum the number of fatal apoplexies in New York in 1868 was 356, in 1886, 762, and in 1893, 1,171. These figures show an increase out of all proportion to the concomitant increase of population. According to the same authority about two-thirds of the cases of cerebral hemorrhage recover from its immediate effects. These statistics emphasize the importance of our subject.

Before attempting to gauge the immediate and remote effects of cerebral apoplexy on the intellect, it will be essential to state what the law requires of the testator to make his final wishes valid in its eyes. From "Redfield's Law and Practice of Surrogates' Courts" I find that a testator has testamentary capacity (1) when he mentally comprehends the nature of his act; (2) when he understands the extent and nature of his property; (3) when he knows the person or persons in whose favor he makes the will; (4) when he is unrestrained in the exercise of his will.

It is to be remembered, however, "that the clearness of comprehension and ability of expression which is required to understand the nature of and enter into a *contract* need not exist. The precise time where incapacity begins cannot be defined by an unvarying rule. Each case must be individually tested in the light of general rules and attending circumstances. The testator must have sufficient memory to give proof of testamentary capacity without prompting and to appreciate the particulars of the business to be transacted. Furthermore, the statue holds that "all persons, except idiots, persons of unsound mind and infants," may devise their real estate; and similarly that persons of certain ages and upward of sound mind and memory may bequeath personal estate.

Bearing in mind this liberal view of the law as to the varying intellectual conditions under which persons are entitled to have their final wishes respected, the opinion expressed by Dr. Gallard in a clinical lecture, delivered at La Pitié, on the post-apoplectic mental condition, is significant. The aphasic, he says, is (1) irresponsible, if he cannot manifest his lucidity by words, pantomime or writing; (2) his intelligence is impaired if he manifest his lucidity by words, pantomime or writing incompletely or sluggishly; (3) he is responsible if he manifest his lucidity clearly and intelligently by words, pantomime or writing.

Without discussing the testator's responsibility in regard to any other acts of a civil or criminal nature, if the last two conditions prevail, he clearly comes within the pale of testamentary competence.

Our next duty is to ascertain how we must proceed in order to establish to what extent the testator is capable of performing intelligent acts: As already indicated, intellect manifests itself by words spoken or written and by acts suggesting the meaning of wishes to be expressed, namely, pantomime or gesture. Disregarding for the present the condition of post-apoplectic stupor or semi-stupor, the suggestions made by Wyllie for the systematic examination of the patient supposed to be suffering from one of the various forms of aphasia are valuable guides.

Written or spoken forms of speech and ges-

[1] Read before the Harvard Medical Society of New York.

tures are examined into separately. The danger of overtaxing the impaired brain of the patient should be always taken into account.

1. How is spoken speech received and interpreted? Is the hearing good? Is there any difficulty in interpreting the meaning of words heard (word-deafness, auditory aphasia)? Replies even by gesture only will show whether or not he understands what has been said. Ask him to put out his tongue, shut his eyes, give his hand. Test especially his power of interpreting nouns and verbs. Ask him to touch his nose, eyes and chin as the parts are named; to whistle, shut his eyes and smile. By refraining from giving the patient hints, by gesture or expression of countenance, the answers to the above questions will determine the presence and degree of word-deafness (auditory aphasia).

2. How is spoken speech produced by the patient? When it is reduced to a constantly-repeated utterance, to one or two familiar words, to an emotional or conventional expression, the whole vocabulary should be carefully noted down. When considerable vocabulary can be used or interpreted, (*a*) record words or phrases showing defective powers of articulation. When there is lalling, stammering or slurring, (*b*) look for evidence of amnesia verbalis and its companion symptoms (articulative amnesia and paraphasia). Record his answer to the request to name ordinary objects and note any difficulty in remembering their names or the paraphrasing of nouns. A case in point of the latter condition is that of Bergman where memory for nouns had disappeared. A window being pointed out to her was designated as "that through which one sees." Mistakes in the use of words should be noted. When the patient is dumb, he should be made to write answers to questions, or, as suggested by Lichtheim, indicate on his fingers the number of syllables in the names of objects shown. If there is paraphasia, ascertain whether the person is conscious or not of the error in use of nouns, verbs, etc.

3. How is speech repeated or echoed? If spoken words reveal word-deafness, they should be repeated over and over again and accompanied by gestures or pantomime to make the person understand what is wanted. It is particularly important under these circumstances to extract evidence of competence to make a will valid. If words are echoed or a phrase attempted, it should be ascertained whether they are spoken understandingly.

4. How is written speech received and interpreted? Is the sight good? Is hemianopsia present? Does he understand questions put before him in writing? If he is speechless let him respond in writing to written requests, such as "Put out your tongue," etc. If there is partial ability to interpret writing or printing, ascertain to what extent it exists by showing him writing or printed matter in books or newspapers.

5. How is written speech produced? Let the patient write his name. Let him give written answers to simple questions. If he writes with ease, let him write at his leisure a history of his case. Note whether there is (*a*) paragraphia, corresponding to written translation of paraphasia; (*b*) the constant repetition of a syllable, word or phrase to express different meanings; (*c*) faults of spelling or syntax.

The right hand may be paralyzed or agraphic. Try writing ability of both hands. The ambidexterity acquired by some persons is remarkable. The patient should be made to write from copy and by dictation and examined as to whether he does so understandingly.

6. Examine as to gesture language—pantomime. Does he understand it? Does he employ it intelligently? Is he entirely incapable of employing it (amimia)? Does he employ the same gesture to express different meanings (paramimia)? Is his mind intoxicated with one particular gesture or series of gestures? It is to be remembered that the intelligent use of gesture language may fulfil the requirements of the law as to testamentary capacity.

7. If the patient has by occupation been familiar with or acquired memory pictures of algebraic, geometrical or other mathematical and scientific symbols, or musical notation, their retention or abolition must be inquired into.

8. Examine as to mind, soul or psychical blindness. Does he recognize ordinary objects and the purposes they serve? Does he recognize persons familiar to him before his illness.

9. Examine as to intellectual faculties and emotional inclination. This will vary with the social conditions of the patient.

The result of the above examination must be carefully noted as each negative or positive observation is made. As a check to possible error in judgment of the examiner, other persons should note independently and coincidently the result of their own observations. The latter may serve to furnish confirmatory evidence.

The data essential to the mental status having been obtained, we proceed to obtain from himself, or his friends, the particulars of the family history, namely, (1) organic or functional diseases other than those of the nervous system, affecting blood relations, giving especial attention to diseases of septic origin, diseases of a wasting character, and to intermarriage; (2) organic and functional diseases of the nervous system. We must not remain satisfied with noting instances of apoplexy, insanity, epilepsy, hysteria, neurasthenia, organic disease of the brain and peripheral nerves, but must obtain information regarding habits, idiosyncrasies and temper of near relations. In a similar manner and with attention to even greater details, if possible, the personal history must be entered upon, from childhood forward, not omitting to note (*a*) educational status; (*b*) psychical influences of occupation; (*c*) mental condition under varying exigencies, namely, temper and emotional inclinations; (*d*) habits.

Before passing on to the consideration of the mental status, accompanying various forms of

aphasia, singly or in combination to which, after eliciting the above information, each individual can be assigned, I wish to consider briefly the apoplectic state. For our purposes three forms of this condition are to be considered.

1. The comatose form, developing ordinarily after hemorrhage large in amount or located near nervous ganglia or tracts of critical importance to cerebration. The condition is a familiar one to every physician. It resembles that of meningeal hemorrhage or brain concussion from head injuries, uremic or diabetic coma, profound alcoholism, and the post-epileptic status. The patient cannot be aroused. The intellectual faculties are in abeyance. The individual is irresponsible and cannot perform a rational act. If the patient survive he passes after a few hours or days into the next state.

2. Post-apoplectic state. Motor paralyses are now evident. Sensory disturbances and aphasias may evince themselves upon investigation. The responsibility of the patient may now be determined by examination on the lines already laid down. The eventuality of an acute inflammatory process around a clot or an area of softening must be kept in mind. Delirium and epileptiform convulsions will supervene to indicate this complication.

3. In a third class we include all those cases in which the acute subjective symptoms are transitory. Partial or complete thrombosis, embolism or hemorrhage in the so-called latent area of the brain are the causative factors. Serous apoplexies belong in this category. Motor and sensory disturbances may be slight. Intellectuality is little disturbed. The individual is usually responsible.

Motor paralysis, including the motor or ataxic forms of aphasia, do not *per se* impair the normal activity of those ganglionic centers and nerve tracts essential in the recalling and evolution of memory pictures necessary to the performance of a rational act. In fact it is not an extraordinary occurrence to see individuals centrally paralyzed, active in the ordinary affairs of life. Cases of pure motor aphasia, that is, a hemorrhage the primary and secondary effects of which are so localized as to invalid only the nerve centers in Broca's convolution, are uncommon. Amimia or paramimia is often and agraphia and paragraphia sometimes associated.

To appreciate the significance to the individual of these lesions, we must bear in mind that impressions conveyed to the cerebral centers are (1) innate or elementary. The appreciation of light, of sound and contact are apparently manifested at birth. According to Roose, "Certain looks, tones and gestures, congenital reflexes, exist among the most distinct races of men from infancy." By a process of storage of memory pictures, for which a selective instinct for certain brain areas also is innate, the (2) acquired or cerebral faculties are developed. Memory pictures stored in the cerebral areas devoted to the reception of impressions from their respective senses, comprise the sum total of education. The association, evolution and emission of these memory pictures is characteristic of á normal mental activity. Its interruption through destructive influences brought to bear on the sensory areas and connecting nerve tracts marks the phenomena of aphasia. Memory pictures most firmly impressed by frequency of reception, or in company with some great emotion or at a time when the brain is in a condition of greatest receptiveness, are retained most tenaciously. They also survive destructive influences the longest. Hence the phenomena of apparent mental intoxication of aphasics with certain words or phrases, such as "yes" and "no" or oaths. (3) Finally under abnormal conditions the emission of associated activity of brain areas is set in motion without the control of the will giving rise to the phenomena of subconscious and unconscious mental activity. These interest us only indirectly.

We are now ready to consider the mental status of each variety of aphasia. That of motor aphasia has already been alluded to as causing in its uncomplicated form least intellectual disturbance. It is supposed to be due to a lesion at the foot of the third left frontal convolution. The patient is dumb or capable of attempting only the simplest words or phrases, which, according to the degree of mental intelligence, are apt or irrelevant (paraphasia). He understands spoken language and partly, at least, written speech. While normal articulation is impossible, written speech is, though exceptionally, retained unimpaired. If this is the case the patient is without doubt intellectually competent, as he evinces his capacity for the evolution of mental language which must precede the formulation of representative signs of ideas. He cannot echo dictation in any form, but copies writing and may write from dictation. Amimia and paramimia may be and often are incidental conditions.

Auditory aphasia refers to damage done to the posterior thirds and of the first and second convolutions of the left temperal lobe, resulting in word-deafness. Spoken language conveys no meaning but written or printed matter does. Auditory intelligence being abolished, the patient, therefore, being almost or quite unable to appreciate word values and coherence, may not be able to make himself understood. His speech may be reduced to an intelligible jargon. For a similar reason echoing dictated speech or writing from dictation is impossible. While writing may be copied without difficulty, writing spontaneously may be impossible or convey no meaning.

Gowers considers will-making incompatible with word deafness. If, however, the visual tracts and the tracts between visual centers and motor speech centers are intact, writing and speech is impossible. The individual under these circumstances is responsible. (A patient of Lichtheim could not understand speech, but could read, write and copy speech.) As the well-known Prof. Lordat, who had lost the power of speech and auditory appreciation, recovered

sufficiently to write a history of his own case. Hallucinations of hearing occur.

Visual aphasia, ascribed to lesions of the angular gyrus of the left parietal lobe, is less serious in its effect on the intelligence than the variety just described. The patient ordinarily understands what is said to him, writes upon dictation and expresses himself rationally.

The memory for the meaning of writing or print is gone, nor can he write spontaneously nor understand what he himself has written upon dictation. Hemianopsia is an incidental condition, a factor also in producing hallucinations. The case of Dr. Mills (Hamilton's System of Legal Medicine) is an excellent illustration of the condition. The patient was a woman sixty-six years old who had light lateral hemianopsia; no pupillary inaction; recognized objects seen, heard, felt, smelled and tasted; recognized persons she met, but this capacity failed; confused names of her four sons; understood what was read to her; did not understand printed or written words; could sign name and write a few short words on dictation, but written words were illegible except the word "cat." Although she recognized objects by sight, hearing and touch, she could not name them correctly on seeing them. Said she knew the name but could not recall it. A stamp she called "ticket" or "letter" and pills "pencils"; knew their uses though she named them wrongly. Called postal card "stamp" and watch "key," saying it looked like a key; a bunch of keys were called "locks", but she evidently knew their use. Could not name pocketbook when held up, but did so quickly when she touched it.

Finally we have to consider the mental status of verbal amnesia, soul blindness, the conduction aphasia of Wernicke. This according to Kussmaul is the severest form, leading to confusion of thought and diminution of intelligence. The patient is ordinarily irresponsible. The lesion is in the concept area of the brain, located by Wernicke in the convolution of the island of Reil. The condition results from the cutting off more or less completely of the connecting nerve tracts between the concept area and the areas in which are stored auditory, visual and motor word memory centers. Patient may understand spoken or written speech and copy writing. There may be inability to echo speech. Paraphasia and paragraphia prevail. The use and understanding of gesture speech may be lost. Bergman's case in which nouns disappeared has already been referred to. Starr gives a case where paraphasia progressed to total aphasia. Though the person knew the disposition he wished to make of his property he could not indicate it by word of speech or writing. The condition may be appreciated by studying Lichtheim's diagram of all forms of possible aphasia. It must be remembered that in the course of weeks or months all forms of aphasia may improve or even entirely disappear.

The following are illustrative cases of apoplectics whose wills were contested. Baltman reported in 1743 the case of a resident of Mindon, Hanover, whose will made by signs was sustained. Another man sixty-three years of age, a hemiplegic and aphasic, made his will by signs, but it was not sustained as his mark was in the middle of the card instead of at the end of it. In the Parish will case reported by Dr. Mills, the first will was made when the testator was fifty-four years of age. The year following had a stroke from which he recovered. Seven years later he became paralytic and aphasic from a severe stroke and developed epileptic fits. The first codicil was made six weeks after the last apoplectic stroke. Four years later he executed a second codicil, five years later, a third codicil. The Supreme Court and the Court of Appeals decided against all three codicils.

Mrs. Fillmore, widow of President Fillmore, whose case is reported by the late Dr. Landon Carter Grey, maniftested symptoms of impaired mentality before she had an apoplectic stroke. She executed two wills within eight months of the stroke. On Dr. Grey's testimony she was judged to be insane and incompetent. The following case is reported by Dr. C. K. Mills (Hamilton's System of Legal Medicine). A man was married to a woman, after he had been living with her and had had children by her. The marriage was legally consummated. After an attack of apoplexy with aphasia, he could answer questions intelligently. The marriage was considered valid and the will in the wife's favor was sustained.

A case in which I was asked to give testimony was that of a woman, over seventy years of age, who had two apoplectic strokes at an interval of about four weeks; after the first stroke she became hemiplegic, spoke sluggishly and with some difficulty, but apparently suffered from no distinct form of aphasia. She understood what was going on about her, gave directions as to household affairs; was able to recall occurrences of recent and remote date, had frequent spells of somnolence. About ten days after the first attack of apoplexy she executed her will. Its validity was sustained by the Surrogate and the case was not appealed.

SURGICAL DIAGNOSIS.[1]

BY JAMES J. MCKONE, M.D.,
OF TACOMA, WASHINGTON.

DIAGNOSIS is the art of discerning a given morbid condition, recognizing its character and distinguishing it from a condition of health or disease of another kind.

The judgment formed in this manner in a narrow sense is simply giving a name to a disease, but from a broader view it consists of something more than this. It shows how the whole organism has been affected from the beginning, the character of the ailment and how the organism as a whole has been affected, or how it has acted locally. The severity of the disease and the pa-

[1] Read before the Pierce County Medical Society.

tient's prospects are arrived at by this method which is alone the sure guide to treatment.

We attain a diagnosis only by having our preception of the behavior in a general manner of the patient sharpened and by carefully combining with it the experience derived from previous examinations. Diagnosis is partly an art and partly a science; an art because it demands a cognizance of the means and their application to arrive at the desired result; a science because it comprehensively takes accounts of general facts and of principles based on those facts.

By surgical diagnosis I mean the differentiation of those diseases which are liable to require operative treatment, but there can be no hard and fast rules at the present time between medical and surgical diagnosis for the one must be associated with the other, as the majority of all surgical cases first seek the physician. It is, therefore, very important for the latter to be well versed in the recognition of surgical affection, as only by the prompt resort to surgery in manv diseases can the patient be given the best means of recovery.

Surgical diagnosis was given prominence as far back as 1500 B. C. when in the Papyrus Ebers then written it says: "If this tumor goes and comes under your finger, trembling even when your hand is still, say it is a fatty tumor, and treat it with the knife, after which treat it as an open wound." The writings at that time also laid stress on stone in the kidney followed by abscess with directions to cut for it, also articles on dislocation and fractures.

In ancient times the surgeon was not supposed to be a diagnostician, but to work only under the direction of the physician, who belonged to the nobility, while the surgeon was inseparably connected with the barber.

The celebrated John Hunter, who lived between 1728 and 1793, did much to encourage the surgeon to be a physician also. The margin between the two gradually grew less until a surgeon became a physician to a greater or less degree, and the surgeon then diagnosed as well as treated his own cases.

It is often said of prominent surgeons that they lack diagnostic ability, this comes in part from the ancient times when they acted simply under the instruction of the physician, but more from the fact that their technic and skill at the present time are so marvelous that their diagnostic ability suffers by comparison, and again the surgeon's mistakes become at once apparent when the disease is laid bare by the knife, while a physician can go on treating a case with no opportunity to disprove his judgment. Taking all the facts into consideration I have no doubt that the surgeon will compare favorably with his brother medical man.

The qualifications of a surgeon were formerly put down that he should "have the eye of an eagle, the heart of a lion and the hand of a woman." The eagle's eye and the woman's hand are still very necessary, but the lion's heart, as it was understood in those days to be one who would not be deterred by the cries and struggles of his patient, since the days of anesthetics has no place in our profession. It also probably refers to the courage required to operate in pre-aseptic days.

The principal qualification of the surgeon at the present time is that he be a good diagnostician, as it is for this purpose he is mainly called in consultation, *i. e.,* to see whether or not the patient is suffering from a medical or surgical disease. For that reason a man who is not a good general practitioner will never become a successful surgeon. For how else would he be able to weigh all the evidence in the different cases. He must know well his anatomy, his physiology, his bacteriology, the natural history of disease and his acquaintance with human nature not too limited. We often see hysterical joints treated for other affections, or two different diseases in the same patient, one a medical and the other a surgical disease. With how many different affections might not a subacute inflammation of the gall-bladder be confounded? Who has not been called to a case of pneumonia and found a patient suffering at the same time from some septic condition in a distant organ? Time and time again we see acute osteomyelitis treated for rheumatism and I might add disease of the hip-joint and aneurism mistaken for this affection. For this reason a general practitioner should keep thoroughly posted on all surgical diseases whether he intends to operate or not. You cannot separate the two. A man may become so expert in one branch that the number of his patients in that particular line will become so numerous he must give his whole time to that department of medicine, he then becomes a specialist because his skill has made him so and long years of practice have particularly adapted him to readily recognize those diseases, but this, I am sorry to say, is not the evolution of the modern specialist. He is a specialist before he is a general practitioner, and every case is diagnosed from the standpoint of his own specialty.

I have said the principal qualification of a surgeon is to be a good diagnostician. This is at times varied with the popular notion that a surgeon should be a good cutter. Now the cutting has very little to do with it. We can teach a man of any mechanical ability in fifteen minutes how to amputate a leg. Any butcher can amputate a limb, but it takes a surgeon to save one. We charge five dollars for doing an operation and four hundred and ninety-five for knowing what to do. In the principal operations the question is to know what to touch and what to let alone. The hand must be trained to feel, the eye to see, the ear to hear and the mind to think. But we may be told this belongs to treatment and not to diagnosis; this is true to a degree, but while one is operating the conditions one meets must be diagnosed as the operation proceeds and in many cases we diagnose by the operation. This fact led many surgeons to group diagnoses of the abdominal cavity,

claiming something existed which did not belong there—when a tumor was found—and that the foreign body must be removed whatever its nature, and there was time enough to diagnose when we had it in our hands. This is sound advice, as a general rule, but there are many exceptions, as when the question arises as to the connection between a certain growth, suppuration or other morbid condition and the general state of the patient, whether it is the cause or effect or is independent.

It would be folly to submit a patient suffering from a benign tumor of the uterus to a hysterectomy, when said patient had a pleura filled with pus, yet I have seen this done under the mistaken idea that the suppurative symptoms were due to the tumor.

In diagnosing a case, first consider the history of the patient. This is one of the most important things in making a correct diagnosis. Find out the length of time the trouble has existed, how it first commenced, the nature of the accident or injury, and the amount of suffering or inconvenience connected with it. You all remember the old story of a college professor who, when lecturing on diagnosis to his students, brought in an unconscious man with a swollen jaw. He then asked the students to diagnose the case without an examination or a history; one said the swelling was a fatty tumor, another said it was a cyst, another said it was a bony tumor of the jaw, and so on, as many different diagnoses given as there were students. Then the old professor opened the man's lips and turned out a quid of tobacco—the man was drunk.

Next comes inspection. This must always be one of our first diagnostic efforts. If the abdominal walls are rigid and fixed, we should suspect peritonitis; if severe pain exists which is relieved by pressure and associated with restlessness, colic may be suspected; if we can see the intestines contracting through the abdominal wall, obstruction is probable, and in these cases, especially if vomiting be present, always inspect the hernial openings; if the prominence is more on one side than the other, then ovarian tumor should be suspected; an enlarged kidney may bulge in the right or left abdominal region, while a descended bladder may occupy the whole abdominal region. The umbilicus should be observed. It is flattened in ovarian tumor and bulges in ascites. Local edema over a tumor frequently shows whether it is a growth or an inflammation. Thinning of the skin is often well marked in ovarian tumors.

Palpation is next performed and is also very important. With the hand flat, feel the edge of the liver; note its size, its shape and degree of hardness; special resistance over any part may point to disease. When a tumor is discovered, palpation may bring out its degree of hardness, size or fixation. Pulsation may be elicited if expansile dependent on aneurism or rapidly growing sarcoma. If non-expansile it may be a solid tumor which rests on the aorta. We may also determine whether the tumor is solid or fluid, movable or fixed. In palpating distinguish whether the tenderness is superficial or deep seated. For instance the reflected pain of appendicitis is usually above the umbilicus, while the deep pain is at McBurney's point. Again, the reflected pain of ovarian inflammation may be in the costal region, while the deep pain is in the ovary itself. Free fluid in the abdominal cavity does not give rise to a splashing sound, while in a dilated stomach when mixed with air this sound may be heard. Vaginal examination for pelvic disease is of great importance. In the case of tumors their connection with the uterus can be made out and the character of the growth may also be determined. If hard nodules can be felt in the peritoneal pouch with a history of failing health, malignant disease can usually be diagnosed. Cancer of the base of the bladder can also be felt with the finger in the vagina.

Rectal examination is no less important than the vaginal. By this means any effusion in the pelvis, the tubes or the ovaries, can be examined; also the pelvic glands and the general contour of the pelvis.

Ausculation must not be omitted. Listen for fetal heart sounds and placental bruit in all cases of suspected pregnancy.

Pain may be absent, but is present in most cases. Note the degree of suffering, how it originated, its location. If it has its chief seat over the cecum or umbilicus, it is probably appendicitis. If it is in the right costal region below ribs and the patient has had several attacks and the pain passes back to the scapula, and especially if some seizures have been followed by jaundice, gall-stones are the probable trouble. If pain is ovarian it is generally referred to the front and down the thighs. Stomach pain usually radiates to left scapula region, while gall-bladder pain radiates to right scapula region. The explanation of this lies in the connection between the sympathetic nerves which pass along the blood-vessels and the corresponding spinal nerves. For instance, in appendicitis, although the disease is of cecal origin, the first pain complained of is nearly always at the umbilicus or just above it. The reason for this is that the appendix receives its blood-supply from the superior mesentric artery and the nerves which accompany it communicate with the spinal nerves at a higher point than those which supply the descending colon. (Warren and Gould.)

To facilitate diagnosis we should always employ all the aids at our command. The microscope, the X-rays which, however, have been somewhat disappointing, for on account of the thickness of the muscles of the loin and the abdomen we have not been able, as we first expected, to make out renal biliary calculi. The X-ray is still, however, quite useful in fractures and dislocations.

We should not overlook the examination of the urine, both chemically and microscopically. The vomited matter and feces should also claim our attention.

Always compare a diseased member with the sound member. When called to an accident in the street or in a public place, where a minute examination is impossible, never venture a diagnosis, because a patient may be injured in several different parts of the body. He might have a compound fracture of the ankle and at the same time a dislocation of the hip. The chances are in the majority of these cases of accidents that the patient when taken home will call his family physician, and if we should overlook an injury which he might discover on account of his better facilities for examination we should surely be blamed and our reputation would suffer in consequence. For this reason we should have the patient removed at once to his home or to a hospital where a thorough examination can be made, calling in a brother practitioner if necessary. Begin at the head, examine the skull, the face, then the neck, passing the hand over the trunk, examine the ribs, then examine each bone separately, if the patient is unconscious and unable to locate his pain. If patient is unconscious and suffering from a supposed injury of the joints or a fracture, give him an anesthetic and examine the part thoroughly, so, if anything should happen in the future, we can at least show that we have done our duty as far as surgical skill can.

STATIC ELECTRICITY IN THE TREATMENT OF SPRAIN.

BY LEONARD C. STANFORD, M.D.,
OF NEW YORK.

BEFORE recounting the following cases, I desire first to describe briefly the method of application. The electricity is generated from a Holtz machine of the largest size. The patient is placed on an insulated platform, which is connected with the negative pole of the machine by a brass rod. An electrode connected with the positive pole by a brass chain gives off the spark, after the circuit has been completed; the length of the spark being from two to four inches. The application is made over and around the painful areas by the positive electrode. The administration lasts from ten to fifteen minutes, and is occasionally broken by a short intermission. This in very short outline was the method of treatment pursued in the treatment of sprain in the patients whose histories in brief are recorded. Most of the injuries occurred on the football field and they offered a wide range for the application of this remedial agent.

Case I.—A. Sprain of ankle. Injury sustained a few hours before treatment. Ankle had been previously sprained and patient incapacitated for two weeks. At time of present injury had just recovered from first. Examination showed ankle slightly swollen, exceedingly tender over internal lateral ligament. Patient walked with a cane. Electricity was used, as described, with marked immediate relief. Patient walked without pain for several hours. There was decided improvement on the following day. Daily applications of electricity were made for five days, when the patient experienced no difficulty in walking. Two or three days later played football with no subsequent injury to ankle.

Case II.—G. Sprain of ankle. Patient was seen day after the accident. Examination showed swelling and tenderness over internal lateral ligament. Patient used cane. He was treated twice a day for two days, daily for four days, every two or three days for two weeks. He walked without pain or limp on the sixth day, but experienced considerable difficulty in playing football from inability to stand on his toes on the injured side. He played regularly about two weeks after the injury.

Case III.—B. Sprain of ankle. Patient was seen immediately after injury. Examination showed right ankle tender and somewhat swollen over both lateral ligaments. Patient on crutches. After one application of electricity, patient walked in office without crutches. Treated twice on subsequent day, daily for three days after. Walked without difficulty on the seventh day. Some few days later, turned the same ankle and received daily treatment for one week. During this time, walked with a cane, at the end of it, without.

Case IV.—K. Seen soon after injury. Right ankle swollen. Marked tenderness over external lateral ligament and head of malleolus. Treated daily for three days. Every other day for ten days. Walked without difficulty in one week. Patient subsequently had persisting pain on pressure over head of fibula, apparently in the bone. This pain was not relieved by electricity. It, however, did not interfere with his walking.

Case V.—G. Patient was seen day after injury. Examination showed some tenderness over internal lateral ligament. No swelling. He limped slightly. There was marked relief after the first application of spark. He walked without pain. Seen subsequently twice, on successive days. Played football about four days later.

Case VI.—McC. Patient was seen soon after injury. Examination showed swelling and tenderness over both lateral ligaments. Patient on crutches. Relieved after the first treatment. Application daily for three days, every other day for two. Walked comfortably on fifth day.

Case VII.—W. Patient was seen on the afternoon of injury. Examination showed swelling and tenderness over both lateral ligaments. Patient on crutches. Treated daily for four days, every other day for two. Marked improvement from the start. Walked easily on the sixth day.

Case VII.—S. Patient was seen immediately after injury. Examination showed ankle very much swollen; swelling reaching well above the ankle. Great tenderness. Patient on crutches. The relief in this case was specially marked. He received daily treatment for six days, every other day for two. Walked with comfort on the eighth day.

Case IX.—W. Patient was seen immediately after the injury. Examination showed the ankle

to be much swollen and very painful. As it was impossible to use electricity at once, cold applications were made until the following day. When seen then the ankle was extensively swollen, the tenderness had somewhat abated. Patient, however, suffered even on crutches. Treated daily for six days. Walked without crutches on the fourth day, without a cane on the eighth day. Played football in about two weeks.

Case X.—McB. Synovitis of knee. Examination showed slight effusion in synovial membrane of the knee. Joint painful. Electricity relieved the pain to some extent. There was not much improvement in several successive applications, therefore other treatment was employed.

Case XI.—L. Patient was seen immediately after injury was sustained. Examination showed the knee joint to be swollen on the inside and very tender. No effusion. Patient on crutches. Treated daily for five days. Walked comfortably at the end of this time. There was marked immediate relief from pain after the application of electricity in this case.

Case XII.—T. Synovitis of knee. Patient had suffered from several previous attacks of synovitis of the knee. He was seen ten days after his last injury. Examination showed the knee to be swollen and painful. The structures about the joint were thickened, there was, however, no effusion. Patient complained particularly of pain on the inside of knee and weakness and he could not walk without support of bandage and cane. Treated daily for several days. At the end of this time the joint was much less painful and stronger. He walked without bandage and cane in one week.

Case XIII.—R. Synovitis of knee. Examination showed marked effusion. No special result followed two applications of the spark, and treatment was discontinued.

Case XIV.—W. Synovitis of knee. Examination showed extensive effusion in right knee joint. Electricity gave no relief, and other means were employed.

Case XV.—K. Synovitis of knee (severe). One application of electricity relieved the pain to a slight degree. Subsequently it seemed unsatisfactory, and patient was treated otherwise.

Case XVI.—O. Muscle bruise of thigh, very much swollen and exceedingly painful. Patient on crutches. The lesion, although extensive, seemed superficial. The patient was relieved at once, and after daily treatment, walked comfortably in about a week.

Case XVII.—O. Severe muscle bruise of thigh. Examination showed extensive swelling and tenderness of structures, extending from knee to hip. Relief from electricity proved but slight, and patient was treated by other means.

Case XVIII.—C. Synovitis of knee. Patient was seen one month after injury had been sustained. Plaster cast had just been removed from knee. Examination showed no effusion. Knee tender on both sides of joint. Patient on crutches, absolutely unable to bear his weight on injured side. Tenderness was relieved to a marked degree after the first application of electricity. Walked without crutches five days later, having received daily applications of the spark. Walked comfortably without pain ten days later.

Case XIX.—C. Woman forty-five years old. Well in every way to one year ago, when she struck her left knee against a table. During the few days following she suffered severely, and was in bed for a week. At the end of this time acute symptoms mostly subsided. She was unable, however, to walk without pain, and this continued some time. Examination at this time showed some swelling on the inside of right knee joint. Slight tenderness on pressure. Cartilage thickened. Atrophy of one inch, measured six inches below patella. Patient walked with a cane and with considerable effort. A single treatment with electricity relieved her pain considerably. This was repeated daily for one week. During this time patient was freer from pain than at any time since receipt of injury. At the end of two weeks walked comfortably for a short distance without any support. At the present time walks everywhere without discomfort. She receives electrical treatment every three or four days. Atrophy January 1st was one-half inch.

The first eighteen cases quoted constitute a small portion of the number of cases treated in a similar way that have come under the writer's observation. They afford, however, sufficient material for a few conclusions.

1. For sprains with little or no effusion, as, for example, sprains of the ankle, the spark affords a very satisfactory means of treatment. There is immediate relief, which lasts from two to four hours. At the end of this time, some reaction follows, depending directly upon the amount of work put upon the injured limb. Aside from this immediate relief, there is a marked permanent improvement in the majority of instances. In the ordinary cases of sprained ankle, daily applications of the spark made for five to seven days were sufficient to remove all lameness, and the patient walked with comfort a day or so later and in many instances played football. Where it was necessary for a man to use his ankle for football, if the joint was somewhat weakened, various means of support were used.

2. In those cases in which effusion was present to any extent, as, for example, synovitis of the knee, the spark, while for a short time relieving the pain when it existed, seemed to have but little effect otherwise. In these cases, however, after the effusion had been removed by other methods, it was a valuable aid in stimulating and strengthening weakened structures.

The results obtained by this method of treatment in injuries of long standing are not generally as satisfactory as in the acute variety; yet, it seems from Case XIX., as quoted, there are certain instances where it may be of great value.

Care should be exercised in its administration, as occasionally an unpleasant reaction follows. This occurred twice in the writer's experience.

In one instance one hour after the administration of the spark a patient treated for a sprain of wrist suffered a chill and rise of temperature. Constitutional symptoms of some severity supervened and persisted for three days. She was, however, in an unsuitable condition at the time of administration, having been confined but two weeks previously. In a second case the patient with a sprained ankle suffered from a chill and rise of temperature an hour after the administration of electricity. Subsequently this attack proved to be typical quotidian malaria, the occurrence of which might have been influenced by the electrical treatment.

MEDICAL PROGRESS.

Roentgen-Rays and Carcinoma of the Breast.—A. CLARK (*Brit. Med. Jour.*, June 8, 1901) has used the Roentgen-rays in carcinoma of the breast. In one case, after such treatment for nine weeks, marked improvement was shown. The tumor diminished in size, the ulceration diminished and became studded with patches of of epithelium; pain was decreased to a marked degree. Later the glands of the axilla became decidedly smaller. The rays are employed five days a week for fifteen minutes at a time. At the end of the nine weeks the patient's general condition was markedly improved, though she received no medication.

Ringworm.—In speaking of the treatment of tinea tonsurans or ringworm, A. RAVOGLI (*N. Y. Med. Jour.*, June 29, 1901) says that any substance capable of producing the casting-off of the epidermis will be sufficient. On the extremities, a solution of bichloride or iodine or a mixture of chrysarobin and resorcin will be sufficient, but when a hairy surface is affected, the follicles become invaded and epilation is usually necessary. If on the scalp a mixture of crude coal oil and olive oil may pe rubbed daily on the scalp by means of a strong paint brush. Pustulation may result, but this is beneficial. Another more elegant method is to use a one-per-cent. solution of bichloride to moisten the sponge attached to the positive pole of a battery and apply this to the diseased area for about one-half hour each day. He believes that children should not be kept from school, but arrangements should be made so that they could be properly isolated and treated at school by the teacher under the direction of the physician. Barber-shops are a very common source of infection and will continue to be so till sterilization of utensils after use is made compulsory by law.

Skiagraphs and Their Medico-Legal Relations.—The indiscriminate employment of skiagraphy for fractures is unnecessary. Most fractures can be diagnosed without this means, but H. GOLDING-BIRD (*Brit. Med. Jour.*, June 8, 1901) says there are two classes of doubtful cases in which skiagraphy is most advisable, those in which certain of the existence of a fracture, the surgeon does not know its extent or exact location, and those in which the existence of a fracture is doubtful. By this means the physician will protect himself. Often the skiagram will show a most irregular outline of bones which have been fractured though, the functional activity of the part involved is perfectly satisfactory. One who is not an expert may mistake epiphyseal lines for fractures. A foreshortened view may resemble in the neck of the femur an impacted fracture. Fracture at the base of the olecranon is simulated when the light is directly over the bend of the elbow. The acromioclavicular joint resembles a fracture. The appearance of a gradual thickening of bone can be produced at will. Fractures may be overlooked. The line of light caused by a fracture can always be seen, though the irregularity of the bone outline may be completely masked, thus hiding a fracture. One may overlook a fracture in ribs or vertebræ. The center of ossification in the ends of young bones may look like detached bone. Bones of the skull (base) with extravasated blood may not seem fractured. As rarely callus does not show in skiagraphs, it may seem as if fracture still exists with separation of the bone ends. Foreshortening and want of parallelism between bone and plate can produce distortion, the latter giving an appearance of gradual thickening or expansion of the bone. The interpretation of skiagraphs must always be made by an expert.

Apical Presystolic Murmurs.—C. C. GIBBS (*Lancet*, June 8, 1901) says that the following conditions are met with when presystolic murmurs are heard at the cardial apex: Obstruction of the mitral orifice, due either to sclerosis or adhesions, or to the invagination of an auricular thrombus; simple dilation of the mitral orifice; roughening of the margins of a normal-sized mitral opening; insufficient aortic valves, with normal mitral opening; a simple dilated mitral opening or a dilated mitral opening with thickened appendages. The author is certain of the fallacy of the Gairdner theory of the presystolic murmur being caused in the auricular systolic blood-current. Anatomical and pathological conditions do not support this conclusion.

Spasmodic Constipation.—Two forms of spasmodic constipation are distinguished by MAZERAN (*La Presse Méd.*, June 22, 1901). The first is an independent affection; the second is symptomatic, depending on a variety of causes, including especially disorders of the genito-urinary tract, traumatism of the abdominal wall, hepatic colic, stone in the ureter, gravel, intestinal parasites, foreign bodies, hemorrhoids, rectal fissures and fistulæ. Primary spasm is most common in young females and neurotic males or brain-workers. There is frequently an exaggeration of the constipation in women before the menstrual period; rarely is there deficient assimilation or loss of weight. There is an absence of dyspeptic history. Sensitive abdomen, meteorism, undulatory peristaltic zones, pseudotumors

due to contraction, tenesmus, passage of odorless gas, gastric hiccough and thoracic constriction, are characteristic. Purgative treatment is absolutely negative and antispasmodics are indicated; belladonna, asafetida and zinc valerianate are useful. Physical measures include the use of the abdominal douche, sitz-baths, massage, and enteroclysis. Curative treatment is above all hygienic.

Influence of Lecithin on Metabolism.—The experiments of DEGREZ and ZAKY (*La Semaine Méd.*, June 19, 1901) as to the effect of lecithin, have important therapeutic application. Injected subcutaneously or administered by mouth to guinea-pigs and dogs, lecithin in doses of 5 to 6 centigrams caused a marked increase in weight. During the period of treatment there was observed a marked increase in urea and in total nitrogen eliminated, and a diminution in the phosphoric acid of the urine. Evidently lecithin favors the utilization of phosphorus in the economy.

Porro-Cæsarian Section for Placenta Prævia Centralis.—A Porro operation for placenta prævia was reported by Lawson Tait in 1899. W. J. GILLETTE (*Boston Med. and Surg. Jour.*, July 4, 1901) reports a similar case. The os was dilated as large as a ten-cent piece and every attempt at forcible dilation was accompanied by hemorrhage which could not be controlled by tampons. The patient had already bled furiously and had a weak pulse of 140. As further hemorrhage threatened her life, Cæsarian section was performed. The uterus could not be induced to contract and free the placenta, so the latter was peeled off manually, after which, contraction being still unobtainable, the uterus was amputated above a rubber cord previously placed around the cervix.

Leucocytes in Gastro-enteric Diseases in Infancy.—The normal leucocyte-count in infants under ten months, according to recent studies by JAPHA (*Jahrb. f. Kinderheilk.*, 1901, p. 179) averages 13,500. The individual count in children of the same weight and age varies greatly. Mononuclear cells predominate, the average number of polynuclear cells being 42 per cent. In dyspepsia, infantile atrophy, and gastro-enteritis there is no change in the proportions of the various sorts of white cells. In follicular enteritis and cholera infantum, with marked intestinal lesions, there is an absolute increase in the total leucocytes and a small relative increase in polynuclear cells. Milder cases of follicular enteritis show no alterations in the proportions of the leucocytes. Japha maintains that the lymphocytosis described in intestinal diseases in infancy does not exist. The fact is that there are many more lymphocytes in infants than are found in adults.

Forced Flexion and Adduction in Sensitive Hip-Joint.—As a temporary measure in cases of extreme sensitiveness of the hip-joint with persistent night-cries, E. H. BRADFORD (*Boston Med. and Surg. Jour.*, July 4, 1901) tried putting out of action the muscles connected with the spasm which caused the cries. The child was etherized and a plaster bandage applied to the limb which was forcibly flexed and slightly adducted. A complete cessation of night-cries followed. A month later the limb was again placed in a straight position with traction and a recurrence of the night-cries took place.

Fixation of Preparations of Blood by Chloroform.—JOSUE (*La Semaine Méd.*, June 19, 1901) recommends chloroform as a fixing agent for cover-glass preparations of blood. After drying in the air the preparation is plunged in chloroform for two minutes and allowed to dry again before the stain is applied. The author believes that this method of fixation results in more perfect coloration than can be otherwise obtained, for example, with Ehrlich's tri-acid stain.

Widal Reaction.—Although four years have elapsed since Widal's publication of his serum reaction, most of his statements, according to TOBIESEN (*Zeitschrft f. klin. Med.*, Vol. 43, No. 1 and 2), are still adhered to, with one signal exception, however, namely, the proper dilution. While Widal stated that an agglutination occuring after a dilution of 1 to 10 is sufficient, most observers are agreed that a safe diagnosis can only be made if it occurs in 1 to 50. The writer has tested the reaction on material collected over three years, using different attenuations, from 1 to 10 to 1 to 200 Of 350 clinically undoubted cases of typhoid the reaction was positive in 329 with 1 to 50; 17 gave the reaction only with 1 to 10 or 1 to 25, while in 2 a weak reaction could only be obtained with a dilution of 1 to 5, and in 2 no agglutination was present during any period of the disease. One hundred and fifty-one cases suffering from various other diseases, such as tuberculosis, croupous pneumonia, bronchopneumonia, influenza, scarlet fever, rheumatism, cerebrospinal meningitis, pyemia, enteritis and infectious diseases of the urinary organs, were also examined with the following results: The Widal was positive 1 to 25 in 4, positive 1 to 10 in 25, and negative 1 to 10 in 122. Of the first four, three died of acute miliary tuberculosis, calculous pyelitis and tuberculous meningitis, respectively, the fourth, suffering from pleuritis probably tuberculous in nature, recovered. Sixty-one healthy persons who never had gone through a typhoid were also investigated. One gave a positive reaction 1 to 25, 8 positive 1 to 10, and 52 negative 1 to 10. It is necessary to carry on the reaction at all times under precisely the same conditions (1) by using the same growth of bacilli, (2) by having the broth of a definite composition, (3) by employing the same temperature and growths of the same age, usually twenty hours. In all cases the slide was set aside for two hours at room-temperature before examined. The earliest appearance of the reaction with relation to the duration of the typhoid proved to be an entirely inconstant factor, though in the majority of cases it was present by the end of the first or beginning of the second week. Two hun-

dred and ninety cases tested in this direction gave in the first week 138, in the second 111, in the third 30, and in the fourth 11. These figures are not, however, very reliable, since it often is difficult to place definitely the beginning of the disease from the history of the patient and since many patients do not present themselves for a serum reaction until already well advanced in their disease. Rarely a reaction is obtained only during the relapse. There is no definite relation between absence or presence of reaction on the one hand and probability of relapse on the other, nor between strength of agglutination and severity of disease, which makes the reaction valueless from a prognostic point of view. With convalescence, the agglutinating power of the blood rapidly diminishes, yet a few cases who were tested one or two years later still gave the reaction in a dilution of 1 to 50 to 1 to 10.

Etiology of Carcinoma.—E. v. LEYDEN (*Zeitschrft f. klin. Med.*, Vol. 43, No. 1 and 2), who strongly adheres to the parasitic theory of cancer, relates how he first saw peculiar bodies in the ascitic fluid of a young girl suffering from ovarian carcinoma. These bodies appeared as large, oval cells which extended pseudopodia in a remarkable manner for from one to two hours, the movements finally ceasing without any subsequent retraction of the processes. Similar bodies were found in pleural exudates of cases of carcinosis, in the fresh juice from carcinoma and melanosarcoma. By accident it was found that a decoction of *Chrondrus crispus* (Irish moss) forms an excellent culture-medium for growing these bodies from small tumor-masses. A number of tumors were then investigated microscopically and in all of them epithelial cells which besides the nucleus contained a number of vacuole-like structures, with central reddish-stained dot, were found. They showed a remarkable resemblance to certain amebæ and could be well distinguished from the granules resulting from degeneration of the cell or its nucleus. The author concludes that in all probability the cancer-parasite is a protozoon and not a yeast. The same subject is treated by ROSWELL PARK (*Buffalo Medical Journal*, July, 1901) who briefly reviews the work done by the Buffalo Laboratory. The arguments he advances in favor of a parasitic etiology are many and well-nigh conclusive. Tumors occur in trees and plants, as well as in the lower animals, which bear a certain resemblance to carcinoma in structure and which are known to be parasitic. The occurrence of metastases, the local infectivity, and, finally, the presence of strange bodies in the cells are highly suggestive. The recent study of the latter has solved the problem. There remains, however, much to be done to investigate the true nature of these micro-organisms, the exact position of which in the animal kingdom is not yet clearly defined.

The Clinical Thermometer as a Medium of Infection.—This subject has recently been investigated by ROSENBERGER (*Proc. of the Phila. Path. Soc.*, May, 1901) who by a series of experiments has shown that the ordinary practice of washing the thermometer in water and subsequently wiping it with a clean towel or keeping in the thermometer case a pledget of cotton moistened with antiseptic solution are insufficient means for its disinfection. Thermometers so treated and subjected to bacteriological examination invariably showed the presence of micro-organisms. As the result of this work he draws the following conclusions: (1) It is possible for the thermometer to be laden with the usual flora of the oral cavity; (2) such bacteria retain their capacity for growth for at least two months; (3) many pathogenic bacteria possess the same capability; (4) each patient should be possessed of a thermometer as his own property, but when this is not possible the thermometer should be thoroughly disinfected before using; (5) the custom prevalent in hospitals of keeping thermometers in disinfecting solutions is to be commended.

Hydrophobia.—Undue importance is undoubtedly attached to many of the startling discoveries of recent years, and this can be readily understood in connection with a disease such as hydrophobia when the popular mind is horrified by the agonizing deaths that are pictured and where so much uncertainty exists in regard to an actual infection. C. W. DULLES (*Med. Rec.*, July 13, 1901) believes that, although the Pasteur treatment is founded upon a scientifically proven basis, the majority of cases which are treated in such institutions are brought there through unwarranted fear and often taken advantage of by the physicians in charge who wish to make the percentage of recoveries as large as possible. Of course, it is impossible to say that a patient, who recovers after being bitten and subsequent treatment without any symptoms of hydrophobia, was or was not really infected, but the enormous increase in the number of cases since the Pasteur method of treatment was instituted leads one to believe that a large percentage were never infected at all. It is somewhat strange that the vast majority of deaths attributed to hydrophobia have followed bites by unsuspected dogs, so that dog-muzzling laws should be made more general and rigid, and the community should have full and constant protection against dog-bites irrespective of questions in regard to hydrophobia.

Books as Carriers of Contagion.—KRAUSZ (*Zeitschr. für Hygiene u. Infectionkrankheiten*, June 18, 1901) has by a series of experiments confirmed the already existing ideas along this line. His investigations were carried on in five different kinds of material, (1) new paper ready for the press, (2) newly printed sheets, (3) newly printed sheets fastened into blocks, but not bound, (4) newly bound books not yet sold, (5) books which had been in use. From

these various sources he cut small strips of paper and under antiseptic precautions introduced them subcutaneously and intraperitoneally into guinea-pigs. Of eleven thus inoculated intraperitoneally three died in forty-eight, fifty-one, and sixty-three hours respectively and showed on autopsy the lesions of purulent peritonitis. All those who died had been inoculated with paper from used books and none of those inoculated with new paper or paper from new unused books were in any way affected. He then inoculated tubes of nutrient bouillon with slips of paper from the above-named sources. Paper from new unused books produced in twenty-four hours very little growth in such bouillon. Paper from old books always showed abundant growth. Guinea-pigs inoculated intraperitoneally with 1 c.c. of a series of such bouillon growths showed the same results as those obtained in his first experiment. Guinea-pigs inoculated intraperitoneally with paper from old books which had been sterilized in the autoclave never showed any effect from such inoculation. Tubercle and typhoid bacilli may remain alive a long time when dried upon paper, the former from twenty to eighty days. The best means of disinfecting books is by means of formaldehyde gas, but when subjected to this they should be so arranged that all the pages are exposed. Books that have been over three months out of use do not need disinfection, as any micro-organisms with which they might have been contaminated would have perished within this time. School-books and books from libraries should be disinfected at regular intervals.

Treatment of Hay-Fever.—In this era of antitoxins it is not surprising that various attempts should be made to immunize patients to diseases which they seem very prone to acquire. H. H. CURTIS (*Med. Rec.*, July 13, 1901) reports the use which he has made of preparations from certain weeds, especially ragweed, and various flowers, in order that by the administration of small doses of this poison the body may develop an immunity to the pollen of those flowers. The fluid extract of ragweed was combined with aromatics and distributed under the name of *Liquor Ambrosia* among a large number of physicians last summer. The reports in a large percentage of cases were most satisfactory, and he believes that the cases which did not respond might have been due to other exciting causes, or that they were given the remedy after the attack had begun. A more thorough investigation is to be made this year.

Cause of Cancer.—A number of propositions in regard to the present status of the carcinoma question are made by N. SENN (*Med. Rec.*, July 13, 1901) and much concise, valuable knowledge is given. Carcinoma is a humor resulting from anatypical proliferation of epithelial cells from a matrix of embryonic cells of congenital or post-natal origin. The law of the legitimate succession of cells holds true in the origin and growth of tumors, both benign and malignant, as well as in the production of normal or inflammatory tissue. The histology and histogenesis of these tumors speak against the parasitic origin. The positive results of implantation and inoculation experiments have so far failed in establishing beyond all doubt the parasitic theory of carcinoma. At present a radical operation is the only rational method of treatment, but, since carcinoma is the result of an erratic, planless cell-growth outside of the range of physiological influences which regulate normal tissue repair, researches should be made to find an agent which will destroy the tumor by causing a degeneration of its parenchyma or which will possess the property of converting embryonic into mature epithelial cells, thus converting a carcinoma into a benign epithelioma.

Diphtheria Bacilli in Noma.—The bacteriological examination of eight cases of noma which have been reported by WALSH (*Proceedings of Phila. Path. Soc.*, June, 1901) shows most interesting facts in regard to the connection of the diphtheria bacillus with this disease. In all of these cases he was able to isolate this bacillus, but only one case showed pure culture of the same. The others showed in addition diplococci and large bacilli, but, as his object was the isolation of the diphtheria bacillus, he did not identify the other micro-organisms found. After reviewing the literature he concludes as follows: (1) True diphtheria bacilli are found in many cases of noma; since this disease is a species of moist gangrene, requiring probably the presence of two micro-organisms, one saprophyte and one parasite, to produce it, it is possible that in those cases where diphtheria bacilli are found they are the causative agents; (2) when pathogenic micro-organisms capable of producing necrosis are found, it is possible that they may be the primary excitant.

Oophoromata and Paroophoritic Cysts.—Malignant tumors in the ovaries of children are histologically distinct from the common forms of cancer or sarcoma and may properly be given the name oophoromata. Their characteristics are that they repeat the connective tissue of the fetal ovary, usually affect both ovaries simultaneously, though not always, rarely occur after puberty, recur locally after removal, may be associated with ovarian dermoids, have a preponderance of cell elements in fetuses and very young children, and toward puberty tend to assume an alveolar arrangement and mimic the structure of cancer. The cysts which arise in the paroophoron are, as a rule, unilocular, and differ from oophoritic cysts in that they do not affect the shape of the ovary until of large size, always burrow between the layers of the mesosalpinx, and are beset in the interior with warts. These warts

are very vascular, bleed freely when handled, and are frequently calcified.

Death Due to Hypertrophy of the Thymus.—While hypertrophy of the thymus, if not arrested, is properly regarded as a fatal disease, TAILLENS (*Revue Médicale*, June 20, 1901) calls attention to the possibility of successful surgical intervention. In cases of sudden death due to cardiac failure there can be no question of treatment, but there is no need to stand idly by and permit a fatal termination in cases in which compression threatens a slower death by asphyxia. Hypertrophy of the thymus has played an important part in numerous medico-legal cases; autopsies have shown this condition to be the cause of death in instances in which poisoning and violence were suspected.

Effects of Yohimbin.—KRAWKOFF (*Klinisch-therap. Woch.*, June 23, 1901) reports the results of the experimental administration of yohimbin in men and dogs. The experiments show a marked fall of blood pressure in dogs, which the author attributes primarily to the action of the alkaloid on the vasomotor center. The hyperemia of the skin, mucous membranes, and genitals which is produced by yohimbin is merely an expression of the action of the drug on the general circulation. This is why yohimbin cannot produce a perfect erection and why it cannot properly be classified as an aphrodisiac. In his experiments on human subjects Krawkoff was unable to obtain the results reported by Mendel. Moreover, symptoms of poisoning were observed to follow the administration of the ordinary dose of 5 millegrams.

Intracerebral Injection of Tetanus Antitoxin.—LETOUX (*La Presse Méd.*, June 29, 1901) reports a case of tetanus following a gunshot wound of the foot. Symptoms developed the day after the injury and ten cubic centimeters of antitoxic serum were promptly injected into each cerebral hemisphere. The symptoms existing at this time continued for several days, but there was no accentuation and in seven days the patient was discharged cured. This is the fourth cure reported by Letoux as the result of intracerebral injections.

Eye Troubles Due to Albuminuria in Pregnancy.—Albuminuric retinitis may occur at any time in pregnancy, but begins especially during the first two months or after the sixth month. It is apt to recur in successive pregnancies. Blindness is rarely caused by the first attack, but each recurrent attack does more damage. In uremic amaurosis there is no immediate visible sign in the retina, but atrophy may ensue. This condition occurs late in pregnancy, usually with other manifestations of eclampsia. It apparently never destroys vision by a first attack. The treatment of both conditions is the treatment of albuminuria and non-use of the eyes, enforced by atrophine and dark glasses. E. W. CLAPP (*Boston Med. and Surg. Jour.*, July 11, 1901) would consider the question of abortion in early albuminuric retinitis of a severe type, especially if hemorrhagic, or if a slight retinitis progresses under treatment; in these cases the life of the child is uncertain anyway and the mother runs grave risks of eclampsia. In cases coming on after the sixth month it is best to wait for other albuminuric symptoms.

Radical Cure of Complete Rectal Prolapse.—The steps of an operation described by JUVARA (*La Presse Méd.*, June 29, 1901) are as follows: Resection of the prolapsed mucous membrane; transverse folding of the muscular wall of the prolapsed portion by a double row of sutures, narrowing of the anal orifice by a U-shaped suture; sewing of the mucous membrane to the anal orifice. The danger to be anticipated is the cutting of the mucous membrane by the tense sutures, with resulting separation of the mucous and cutaneous surfaces and subsequent infection of the exposed area. The operation corresponds substantially to that of Delorme.

Inversion of the Tunica Vaginalis for Hydrocele.—This operation is easy to perform and appears to result in cure of the hydrocele. Many operations have been recorded within the past five years by R. H. GREENE (*Jour. of Cutan. and G.-U. Diseases*, July, 1901) with a history of no unfavorable result as regards suppuration or neuralgia of the testis. In the absence of clinical data extending over a long period of time no conclusions can be drawn as to the effect of the operation in causing atrophy of the testicle.

Congenital Pelvic Malposition of the Kidney.—Pelvic malposition of the kidney is uncommon but important in women. A case reported by DEWIS (*Boston Med. and Surg. Jour.*, July 11, 1901) showed on examination a movable, firm, smooth, notched mass lying behind and to the left of the uterus, as sensitive as the ovaries to palpation. The urine was normal. After five years of clinical treatment for backache, operation was resorted to. Celiotomy revealed a retroperitoneal tumor lying over the promontory of the sacrum, embedded in a soft, thick capsule. After exposure of kidney cortex the incision through the fatty cushion was closed with catgut. The blood-supply of the misplaced kidney could not be made out nor the ureter located. Malposition of the kidney does not seem to interfere with normal function, though it does predispose to complications. There is little aid to diagnosis; the sensitiveness to touch is similar to that of the ovary; when there is malposition there is usually marked lobulation; the "tumor" is always retroperitoneal, with or without mobility. The foremost consideration is avoidance of complications.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

AMERICAN STERILITY.

ONE of the most interesting discussions at the last meeting of the American Medical Association concerned the constantly growing reduction of the birth-rate in this country during recent years and the increasing absolute and relative sterility of American marriages. Dr. George J. Engelmann of Boston read a paper on the subject the statistics of which will be found in our report of the Section on Obstetrics and Diseases of Women of the American Medical Association (MEDICAL NEWS, July 13, 1901, p. 78).

A century ago the sterility of American women was but 2 per cent., the lowest of any population in the civilized world and the average number of children to a marriage was six. At present the national sterility is said to have risen to the alarming figure of 20 per cent. and the average number of children to the marriage is but two. This certainly represents a state of affairs which, if true, deserves serious attention, and all the more so since all the civilized countries are now waking up to the realization that factors are at work for the reduction of population in our advancing civilization that threaten to far more than neutralize the gain in numbers that might be anticipated from sanitary improvements and reduced mortality.

Aside from the mere fact of actual numerical decrease of native inhabitants, a misfortune that already stares France in the face and is not far distant for the United States if present conditions continue to obtain, there are certain ethical considerations that "must give us pause" in this important matter. The conservative editor of a periodical so little sensational as *Harper's Magazine* had very opportunely some words of warning on the subject in the July number. As a side issue in the discussion of modern love and love stories, he speaks of "that revolution through which woman has come to live for herself—for her individual development, rather than for the race." He adds: "If we take a narrow and aristocratic section of contemporary humanity the result seems disastrous. It has been estimated that in fifteen consecutive blocks on upper Fifth Avenue, there are but fifteen children. And, taking a more general view, we can not but consider the denial of motherhood to so many women, whether it be voluntary or involuntary, the saddest tragedy of our modern life."

This is, of course, a pregnant aspect of a great social question. As physicians we are much more concerned with it than might at first sight appear. Undoubtedly there is a tendency in the up-to-date physician to advise too readily against maternity and its attendant cares. It is always a question whether the childless woman or the mother wrapped up in every phase of the health of a single child is really in the end less free from care than her sisters with children and their concomitant duties. Occupation of mind and a definite purpose in life are often the best remedies that can be prescribed for the nervous woman whose time hangs so heavily on her hands that morbid introspection and magnification of symptoms become the burden of existence. While at present the weight of medical influence is exerted toward the limitation of families, it would seem to be safer physically and morally to throw it rather on the other side of the scale so that larger families than are at present the rule would become the mode.

Prophecies are always dangerous things—for the prophet, at least—yet at times they teach the lesson of present tendencies better than any mere review. Mr. H. G. Wells, in a series of articles of forecast called "Anticipations" that have appeared in recent numbers of the English *Fortnightly Review* and the *North American Review*,

lets his prophetic spirit attempt to foreshadow some of the results that may flow from sterile marriages. "Will a generation," he asks, "for whom marriage will no longer be associated with the birth and rearing of children, or with the immediate coöperation and sympathy of husband and wife in common proceedings, retain its present feeling for the extreme sanctity of the permanent marriage bond?" This seems a far cry from the present *laissez aller* conditions. It may even appear too wanting in confidence for the future of the race to anticipate serious ethical demoralization from what is apparently only a little selfish withdrawal from family cares in this generation. Mr. Wells' prophecy becomes more interesting from this standpoint as it proceeds. He foresees even the loss of the present respect for woman and her character if she should continue to shirk her plain duties to the race.

Will the agreeable, unemployed, childless woman, with a high conception of her personal rights, who is spending her husband's earnings or income in some pleasant, discrepant manner—a type of woman there are excellent reasons for anticipating will become more frequent—will she continue to share the honors and privileges of the wife, mother and helper of the old dispensation? And, in particular, will the great gulf that is now fixed by custom between her and the agreeable unmarried lady who is similarly employed remain so inexorably wide? Charity is in the air and why should not charming people meet one another, and are either of the ladies to find the support that will enable them to insist upon the monopoly that conventional sentiment so far as it finds expression concedes them? The danger to them of the theory of equal liberty is evident enough.

These startlingly plain words from non-medical observers are stronger than any protestations that were made at the meeting of the American Medical Association, though there the subject was treated with ungloved hands. The consensus of opinion among candid and unselfish-minded students of the question shows how serious and how urgent are the dangers pointed out. This is not a question to be discussed sensationally and then allowed to drop, because there is no complete practical solution of the problems it involves near at hand. Factors for the simplification of the problem we have at command and they must be employed. The recognition of the dangers ahead is of itself a step in the right direction. Medical influence can accomplish some of the beneficent purposes of avoiding the serious evils and the propaganda of right-minded views in the matter of the limitation of families will help to ward off threatened dangers.

SPATE CHAIRS AND HYGIENE.

OWING to the lull in newspaper news due to Mrs. McKinley's improved health, the dying-out of the smallpox scare, and the cool wave that put a quietus on the death-rate, the columns of our New York dailies have been foaming over with a sentimental fizz of democracy and philanthropy that is swallowed without discrimination by a thirsty public.

The Spate-chair fracas is enlivening the dull monotony of midsummer with its free comedy in Madison Square, and the stay-at-home New Yorkers are grateful for the amusement. But the *Sun* takes the matter seriously. "No, the parks are for the public, undistinguished by their bank accounts," is the solemn fiat. It is "principle" that the *Sun* stands for. Decency, cleanliness, the public health are naught compared with the principle of making no distinction between the tramp and the millionaire in the matter of sitting down.

When it comes to locomotion, the millionaire may run his automobile, the well-to-do man may hire a hansom, the thrifty citizen may pay for a seat in a park carriage, and the poor man may walk; but when it comes to sitting all men must be free and equal, free to make themselves absolutely unbearable to their fellows, and equal to the occasion in disseminating the diseases that one and the other are enduring.

It is a disgrace to our city that the idea of paid chairs is so late in reaching us. It is a well-established fact in cities of older civilization, and the fuss and riots that have attended their establishment make us think of that bygone spirit of certain Western gentlemen whose notion of freedom and equality consisted in defying society to make them put their coats on when they came to the dinner-table.

We wish to sharply remind our fellow citizens who are paying the taxes that the good that is done by establishing breathing-places for the people downtown is just about balanced by the evil that is done by the city's laxity in matters of cleanliness and in just such details as this by which every respectable citizen is exposed to disease in the public parks.

The trained eye of a physician has seen in

Madison Square, within the past year, a man with smallpox stretching himself comfortably along a bench, a dozen men with well-developed cases of barber's itch, ringworm, and other scalp diseases by the score, children with eruptive pustular diseases, and contagions of every kind, to say nothing of the profuse expectoration of tuberculous sputum.

A disinclination to sit on the same bench with a man who is covering his immediate vicinity with tobacco-juice, or with one with filthy social habits, or a third who is sleeping off a night's debauch, undoubtedly shows a haughty spirit of class discrimination which is evidently what the *Sun* intends to rebuke, but we implore this powerful journal to waive for a moment its fundamental principles of democracy, and to seriously consider the fact that the Spate chairs are a long step in advance in matters of comfort and also of health.

A NEW BELLEVUE.

THE fires of criticism have been casting a ruddy glow about this hospital and its management for the past year, and it is to be hoped that we may see the fruition of the plan for a new hospital arise from the ashes of the old. The abandonment of the present Bellevue Hospital buildings and the construction of new and modern buildings have been a dream of the hospital physicians for years. The recent recommendations of the State Board of Charities at its last regular meeting come, then, with special significance. It recommended as follows:

"*Whereas,* The State Board of Charities, having in view the fact that the demands upon Bellevue Hospital are greater than upon any other hospital in this country, and its frequent and thorough inspections having convinced the board that the main buildings of the said hospital are too old and ill adapted to their purposes to be sufficient to meet the proper demands of the service, and being also convinced that the only remedy for present conditions is in a new hospital; it is therefore

"*Resolved,* That the authorities of the city of New York are hereby urged favorably to consider the subject of the erection of a new and modern hospital to take the place of Bellevue as soon as possible. It is further

"*Resolved,* That in the opinion of this board the compensation of attendants and other employees in Bellevue Hospital should be reasonably increased so as to secure the services of competent and satisfactory employees, and that suitable provision should also be made for their care in order that the services of such competent and satisfactory help may be retained."

May the good work go on and the opening of the century see a "new Bellevue," with new and modern buildings, under the control of its new board of managers, which will prove a fitting complement to the medical work of this great city.

OCULAR MOVEMENT AND VISION.

WE are apt to think of the physiology of the eye as almost absolutely settled. However, observations are being constantly made that lead to advances in our knowledge of the visual functions. Even the anatomy of the optic tract is by no means definitely known. Ramon y Cajal, on his visit to this country for the celebration of the decennial anniversary of Clark University, took the histology of the optic tract for the subject of his address. It is evident from his work that the visual apparatus taken as a whole appears more complicated the more we learn of it, and that our knowledge of its details is only just beginning. Not long ago Griff pointed out that even the minute anatomy of the terminal portion of the optic nerve in the retina was not settled. He demonstrated that there are in the retina connecting nerve-fibers which run parallel to the surface in certain of the retinal layers. All the cellular layers of the retina seem to have these connecting fibers, so that stimulation of one or more cells excites nerve impulses in a series of cells. This summation of stimuli produces the effect upon the visual cortex.

The complexity of the visual apparatus thus demonstrated makes it clear that for normal function not only must the eye and, especially, its neural appendages be in good physiological condition, but very definite physical conditions must be fulfilled for the attainment of satisfactory vision. These anatomical considerations may help us to understand the results of a recent set of observations made in the psychological laboratory of Wesleyan University. Prof. Raymond Dodge thinks that he has proven that the eyes when in motion can distinguish nothing in any complex field of vision. In order to see any object at rest the eye must remain motionless looking at some definite part of it for an appreciable length of time. If the eyes move they see noth-

ing for about one-twentieth of a second. Prof. Dodge thinks that this explains the success of those sleight-of-hand tricks in which rapid movements of the fingers are absolutely unseen. This fact also makes it clear why in boxing, fencing, etc., the eyes must be made to dwell upon some comparatively fixed point if they are to give due warning of the movements of an adversary.

Prof. Dodge's observations also throw light upon reading and the manner of its accomplishment which is not by a continuous movement, but by a series of pauses during which not separate letters, but groups of letters are recognized. This serves to encourage the idea now applied in modern teaching that the child should not be first taught its letters, but the significance of groups of letters. The letter is only an artificial word element not correspondent with the true psychologic elements of reading vision. Needless to say, this subject is most important since the question of the use and abuse of the eye muscles and the effect upon the general system of nervous reflexes from the neuromuscular eye mechanism is as yet under discussion. Many an obstinate headache that is often accompanied by digestive disturbance has its origin in this complex apparatus. Light on the matter is most welcome, especially as it is suggestive of an entirely new order of ideas on an old subject.

ECHOES AND NEWS.

NEW YORK.

Smallpox Closes a School.—One of the vacation schools of Brooklyn occupying the building of Primary School No. 88 has been closed by the Department of Health on account of the prevalence of smallpox in the neighborhood.

Removal of Patients from Kings County Hospital.—The State Board of Charities has ordered that the mentally defective and epileptic patients of the Kings County Hospital and Almshouse must be removed to the State Insane Asylums as soon as possible in order to relieve the overcrowded condition of the former institution.

Increased Water Supply for Brooklyn—The danger of the annual water famine in Brooklyn has been very largely averted by the recent heavy rains. The amount of water in the borough reservoirs was increased by 51,965,000 gallons between July 3d and 14th.

Sanitary Conditions at Rockaway Beach, L. I.—The sanitary conditions at Rockaway Beach, L. I., for the past two weeks have been of the worst owing to the lax methods employed by the garbage contractors of that place. Their failure to fulfil their contracts has resulted in the cancellation of the same by the authorities and the extra-allowance of $15,000 to the Department of Highways which will undertake the work.

Disposal of Garbage.—The question of the disposition of the garbage of Manhattan and Brooklyn has not as yet been satisfactorily settled. The bid of the Sanitary Utilization Company, located at Barren Island, which has held the contract for the past six years, has been refused by the Board of Estimate which insists that the contract must run one year instead of five, as was formerly the case.

Long Island College Hospital Appointments.—Dr. Ralph H. Pomeroy has been appointed lecturer on obstetrics, Dr. John O. Polak, lecturer on gynecology and obstetrics, Dr. William F. Campbell, professor of anatomy, to take the place of Dr. W. W. Browning, deceased, Dr. Warren S. Simmons, adjunct professor of anatomy.

Anthrax Prevalent in New York State.—Anthrax has made its appearance among several herds of cattle in the west of New York State at Oneida.

Manhattan Dermatological Society.—A regular meeting was held on Friday evening, June 7th, at the residence of Dr. B. F. Ochs, No. 120 West 120th street, with Dr. Wm. S. Gottheil in the chair.

Dr. R. Abrahams presented a child, seven months of age, with a *congenital nævus* of the left side of the nose near the inner canthus. Treatment by electrolysis was advised. Alcohol injections are dangerous in this locality, but useful for small nævi. Dr. Geyser recommended the use of a positive galvanic gold or platinum needle inserted to the depth of three or four lines and with a current of one and a half to two milliamperes. This produces an adherent clot. Dr. Bleiman preferred a radical surgical operation. Dr. Ochs thinks the platinum needle best and Dr. S. S. Cocks prefers the negative needle. Dr. J. Sobel said alcohol injections cause pain and edema and ulceration about the eye. Electrolysis would benefit the superficial vessels, but there was a bogginess below which would be difficult to cure. Dr. Gottheil spoke of the dangers of thrombosis and embolism from injection. The enormously dilated veins below would cause trouble in treatment. He would advise surgical intervention.

Dr. J. Sobel presented two cases of *ichthyosis* in a boy eleven years of age and a girl aged three. Both were born with normal skin and three months later the present condition appeared. Four other members of the family are similarly affected.

Dr. B. F. Ochs presented a young woman with *psoriasis guttata,* in whom for ten years this condition had recurred every summer and disappeared spontaneously in the fall. Dr.

Gottheil mentioned a case of *psoriasis* in which the attacks were very materially benefited by rest in bed and milk diet.

Dr. Gottheil presented a classical case of *acne necrotica.* In a man about forty-five years of age there appeared since childhood typical lesions at the hair margin, temporal regions and naso-labial fold. Numerous scars were present. The man is otherwise healthy. Treatment at present consists of exposure to the arc-light. Dr. Ochs considers it typical. Drs. Oberndorfer and Sobel spoke highly of white precipitate ointment and mentioned the danger of recurrence in this affection. Dr. Kinch inquired whether sulphide of calcium would not benefit these cases. Dr. Abrahams advises iodide of potassium internally.

Dr. J. Sobel presented a patient with *seborrheal eczema* of the chest, back and abdomen. The lesions were red, scaly and circinate in places. Dr. Bleiman would agree as to the diagnosis although the lesions are not typical. Dr. E. S. Cocks agreed with the diagnosis. The only condition which it resembles is pityriasis rosea and this he excluded. Dr. R. Abrahams considers it herpes tonsurans maculosus et squamosus. The presence of rings speaks against seborrheal eczema. Dr. Gottheil would call it generalized ringworm and erythema multiforme. Dr. Ochs inclines toward a diagnosis of herpes tonsurans, yet there is seborrhea with it. Dr. Oberndorfer remarked that he has seen many cases of seborrheal eczema with annular lesions, many lesions of seborrheal eczema with perfect rings.

Dr. R. Abrahams presented a patient with *lichen planus* of the dorsal surface of the hands and wrists. Drs. Bleiman, Ochs and Oberndorfer said that at present it is difficult to make a diagnosis. Dr. Sobel thought that at present the lesions were not destructive of any affection. The extensor surfaces of the wrists would seem to speak against lichen planus. Dr. Kinch considers it eczema. Dr. Gottheil remarked that in the retrogressive stage an eczema papule may resemble lichen. Dr. Gottheil presented a case for diagnosis. The patient stated that six weeks ago the face became affected. It now presents small papular elevations with sebaceous crusts. On the left hand there is an almost complete circle of papules progressing from the center, on the right hand some staining and old scar tissue. Dr. R. Abrahams considers the affection of the face lupus erythematosus and that of the hand herpes tonsurans. Dr. Kinch said it is suspiciously like a syphilide. Dr. Bleiman considers it a tuberculous process. Dr. Oberndorfer looks upon it as a syphilide. Dr. Ochs thinks it syphilis and Dr. E. S. Cocks lupus or syphilis. Dr. Sobel thought syphilis was to be considered, but that the diagnosis was most likely erythema multiforme. Dr. Gottheil said that the history, the staining, and the face speak for erythema multiforme.

Dr. B. F. Ochs presented his patient with resolving syphilis. Marked improvement had taken place under iodide of potassium and bichloride.

PHILADELPHIA.

Paperhangers Want Walls Scraped.—A committee of the Paperhangers' Union has prepared a circular letter to prominent Philadelphia physicians, asking them to give their views upon the necessity of scraping the walls of houses about to be repapered as a hygenic measure. In the event of favorable replies being received, petitions will be sent to the Board of Health and Councils urging that compulsory legislation be enacted.

Hospital for Braddock, Pa.—It is reported that Mr. Charles M. Schwab, President of the United States Steel Company, will give a hospital, to cost approximately $250,000, to Braddock, Pa. The plot of ground on which the proposed institution will be located is one mile from Duquesne and an equal distance from Homestead and Braddock, and is one of the most desirable in Alleghany County. Car lines will be operated to insure quick transportation to the injured.

New Children's Hospital.—It is reported that the 16-acre tract of land opposite Carnegie Institute in Pittsburg is to be the site of a children's hospital which Mr. H. C. Frick intends to build and endow. The site cost Mr. Frick $950,000.

Free Hospital for Poor Consumptives.—A tract of 215 acres has been purchased in the Blue Mountains near White Haven, Pa., as a site for the proposed sanitorium for poor tuberculous individuals. It varies from 1,500 to 1,800 feet above sea level and is said to be an ideal location. The bill appropriating $110,000 for the erection of the necessary buildings is now before Governor Stone. By the terms of the bill $100,000 will be used for the construction of the hospital buildings, which will be arranged on the cottage plan, and the remaining $10,000 will be used in the treatment of the tuberculous poor in Philadelphia. Each year the State gives about $1,000,000 for the maintenance of free hospitals, but until this year nothing has been done in behalf of the tuberculous poor. It is estimated that 6,000 deaths occur annually in Pennsylvania from this disease and that one-third of the sick poor are tuberculous.

The State Board of Health.—This body held its forty-ninth regular meeting at the Asylum for Chronic Insane near Wernersville on July 11th. Secretary Lee presented a resolution requesting an appropriation of $3,000 from the Emergency Fund for the suppression of smallpox. This was forwarded to the Auditor-General at Harrisburg. It is stated that twenty-four points in the State are affected and that there are fully 2,000 cases in Pennsylvania at present. The sanitary con-

dition of the United Brethren camp-meeting grounds at Mt. Gretna was condemned as bad and the officials notified that their resolution of last year must be obeyed. Dr. Samuel T. Davis of Lancaster was unanimously re-elected president of the board and Dr. E. G. Madson of Pittsburg was appointed bacteriologist for Western Pennsylvania.

To Suppress Smallpox.—The residents of Ashland are thoroughly alarmed over the spread of smallpox in that vicinity. At a special meeting of the Borough Council recently, $1,000 was appropriated to stamp out the disease. Reports from Pittsburg are more favorable. At present ten patients are in the City Hospital and of these six will be discharged in a week. The others are not dangerously ill. The free vaccination of the poor continues, as usual, three days a week.

Hospital Protests Appropriation Cut.—With an authorized capacity of 1,710, the State Hospital for the Insane at Norristown, Pa., is accommodating 2,138 patients, and on this excess of population over space is based a vigorous protest against the Governor's proposed cut in the $128,500 appropriated by the Legislature to this institution. The proposed building for nurses and attendants, it is urged, are necesary from a humane standpoint, patients and their caretakers suffering from the present inadequate facilities. The two buildings desired for the employees would each accommodate 150, whose removal from the wards, it is maintained, would provide quarters for practically all of the 428 patients in excess of the authorized capacity, nearly all of whom are now sleeping in the halls.

Alleged Malpractitioner Held.—Coroner Dugan recently committed Mrs. Elizabeth Geverand to prison on the charge of causing the death of Mary Sullivan, aged twenty-nine years, by criminal malpractice. The autopsy showed that death was from peritonitis following injuries.

CHICAGO.

Dean of Northwestern University Medical School.—Owing to the illness of Dr. Frank S. Johnson, Dr. N. S. Davis, Jr., succeeds him as Dean of the College. Dr. Davis was formerly the Secretary of the College. Dr. Davis' position will be filled by Dr. Arthur R. Edwards. Dr. Edwards has long been actively connected with the College.

Hospital-License Law Valid.—Assistant Corporation Counsel Arthur has rendered an opinion in which the Corporation Counsel concurs, that the hospital-license law now in vogue, that law under which Health Commissioner Reynolds has cited Dr. John Alexander Dowie to appear in court, is a good and valid ordinance. Dowie claims Zion is not a hospital, and that he is not amenable to the ordinance. It has been decided that Dowie must take out a hospital license.

Organization of Trained Nurses.—Trained nurses of the State have formed a permanent organization, termed the Illinois State Association of Nurses. The primary object of the organization is to secure State legislation looking toward the passage of laws prohibiting the practising of nurses without a diploma granted by a training school.

Delegate to the Tuberculosis Congress in London.—Health Commissioner Reynolds has left for Europe, bearing credentials showing his appointment as delegate to the British Congress of Tuberculosis, to be held in the Queen's Hall, London, July 22d to 26th. Dr. Reynolds will also attend the meeting of the British Medical Association at Cheltenham. Among those who will attend the Tuberculosis Congress from this city are Drs. John A. Robison, W. Byron Coakley, and Willis O. Nance.

Changes in the Medical Department of the Illinois National Guard.—Major G. Frank Lydston, surgeon, and Lieutenant E. N. Elliott, assistant surgeon, assigned to Second Infantry, have tendered their resignations which have been accepted. Dr. B. S. Rogers has been commissioned major and surgeon; Dr. B. McPherson Linwell, captain and assistant surgeon, and Drs. F. W. Jay and F. Gregory Connell have been commissioned first lieutenants and assistant surgeons, and assigned to the Second Infantry.

Northwestern University Medical School Alumni Association.—The annual meeting of this Association was held recently. Dr. William A. Mann of Chicago was elected president, and Dr. Henry B. Hemenway of Evanston, secretary.

Formaline in Hospital Milk.—It is reported that poison has been found in the milk furnished the patients in the County Hospital. Samples submitted to the city chemist upon analysis have been shown to contain quantities of formaline sufficient to cause or hasten the death of sick persons. Patients had complained of the milk, and declared it tasted "funny." Warden Daniel D. Healy agreed with them, and promptly had samples sent to the city laboratory. The report rendered by the city chemist condemns the milk for all uses, and leaves the venders of it liable to prosecution by the Health Department.

GENERAL.

Opportunity for Young Doctors.—The recent appointment of forty-five assistant surgeons in the army leaves upward of eighty vacancies in that grade yet to be filled. The large increase in the number of medical officers provided for in the reorganization of the army present opportunities to an extent never heretofore afforded for young physicians to enter the military service. Previous service is not a prerequisite to candidacy, physicians from civil life having an equal chance for appoint-

ment with those who have been or are now in service. Examinations will be resumed in Washington early in September next. For information regarding the service see the MEDICAL NEWS of April 27, 1901.

Another Fraud.—We are indebted to the editor of *Success* for the following warning: A man, calling himself "R. G. Stearns," is swindling physicians in various cities, through offering them a clubbing combination of from eight to twelve magazines and charging therefor $4 or $5. During the month of April he operated in New Orleans, La., Memphis, Tenn., Louisville and Lexington, Ky., and in the first part of May was in Detroit, Mich. So far as we have learned he has worked entirely among doctors and dentists. His method of working is to enter a doctor's reception-room and from a grip which he carries take a number of magazines and display them on the table telling the doctor that he can have this outfit sent him for twelve months for $4. He is described as a smooth talker, twenty-five to thirty years of age, about 5 feet 9 inches, rather slim, weighs about 140 pounds; he has a dark complexion, dark curly mustache, and is a Jew. When in Detroit he wore a light suit of clothes and black derby hat. He uses a receipt which he has had printed with our firm name and address at the top, and a line above the signature reads, "Agent is Authorized to Collect Subscriptions in Advance." He usually includes *Munsey's, Pearson's, McClure's, Review of Reviews, Cosmopolitan, Puck, Judge, Black Cat, Woman's Home Companion,* etc., etc. As he is liable to visit your city, we would suggest that you notify your friends in regard to his methods, and this may probably lead to his apprehension.

Plague Ravages in Egypt.—The United States consular representative at Cairo has informed the State Department that the bubonic plague which prevails in many of the towns of Egypt is of a virulent and destructive type, and on account of its rapid development and the exceptionally high rate of mortality, general apprehension and alarm prevail throughout the country. During the week preceding June 19th, there were twenty-three cases reported, twenty-one of which were at Seagazig and two at Minieh. Sixteen cases were admitted to the hospital and five were found dead outside of the hospital at the former place. Of those admitted to the hospital six died.

Fraud Order Against the Magnetic Healing Institute of Battle Creek, Mich.—Postmaster-General Smith has issued a fraud order against J. E. Batdorf & Co., otherwise known as the Magnetic Healing Institute of Battle Creek, Mich. The "institute" advertised that to any one sending "a lock of hair, with age and sex, including four cents postage," they would send a diagnosis of any or all diseases which the patron might have. To those sending the required lock of hair and postage, the concern sent an appalling list of diseases which the owner of the hair was asserted to be afflicted with, and a price list of medicines to suit the various ailments. To those wishing to be cured by the month, the institute was willing to give special rates. A post-office inspector, a remarkably perfect man physicially, filled in one of the institute's blanks, enclosed a lock of hair and four cents, and was informed by return mail that he was afflicted with eleven malignant diseases in various stages. The medicines sent by the institute were claimed by patients to have been worthless. The Postmaster-General, considering that the institute was not conforming strictly to the spirit or letter of the postal regulations, denied Dr. Batdorf the use of the mails. A more rigorous application of this ruling would rid this country of hundreds of other such imposters.

Enno Sander Prize.—The Enno Sander Prize has for 1901-1902 been generously increased by its founder to consist of a gold medal, valued at one hundred dollars, and one hundred dollars in cash. The subject for this year is "The Most Practicable Organization for the Medical Department of the United States Army in Active Service."

1. Competition is open to all persons eligible to active or associate membership in the Association of Military Surgeons of the United States.

2. The prize will be awarded upon the recommendation of a Board of Award selected by the Executive Committee. The Board will determine upon the essay to which the prize shall be awarded, and will also recommend such of the other papers submitted, as it may see fit, for honorable mention.

3. In fixing the precedence of the essay submitted, the Board will take into consideration — primarily — originality, comprehensiveness and the practicability and utility of the opinions advanced, and—secondarily—literary character.

4. Essays will consist of not less than ten thousand, nor more than twenty thousand words, exclusive of tables.

5. Each competitor will send three typewritten copies of his essay in a sealed envelope to the Secretary of the Association, so as to reach that officer on or before February 28, 1902.

6. The essay shall contain nothing to indicate the identity of the author. Each one however will be authenticated by a nom de plume, a copy of which shall, at the same time as the essay, be transmitted to the Secretary in a sealed envelope together with the author's name, rank and address.

7. The envelope containing the name of the successful competitor will be publicly opened at the next succeeding annual meeting of the Association, and the prize thereupon awarded.

8. The successful essay becomes the property of the Association of Military Surgeons of the United States, and will appear in its publications.

Board of Award, 1901-1902.—Honorable WILLIAM CARY SANGER, *Assistant Secretary of War;* Brigadier General GEORGE MILLER STERNBERG, *Surgeon-General U. S. Army,* and a distinguished officer of the line to be announced later. JAMES EVELYN PILCHER, *Secretary,* Carlisle, Pa.

Obituary.—Dr. George H. McMurray died of diabetes in Glens Falls, N. Y., on Friday at the age of thirty-six years. He was educated at Fort Edward Collegiate Institute and the Albany Medical College, and at the time of his death was a member and the secretary of the Pension Examining Board which meets in Glens Falls.

Dr. James Marvin, at one time Chancellor of the University of Kansas and later Superintendent of the Haskell Industrial Indian School, died at Lawrence, Kan., Tuesday. He had been an invalid for years.

Dr. John F. Trenchard, a former well-known physician of Philadelphia, and at one time a member of the City Council, died at Fairton, N. J., July 16th, aged eighty-one years.

CORRESPONDENCE.

MEDICAL NOTES FROM THE PAN-AMERICAN EXPOSITION.

[From Our Special Correspondent.]

THE Medical Bureau of the Pan-American Exposition was established last August, and from that time until the present writing, June 30th, 1,950 cases have been treated by the staff. The hospital, which is situated near the West Amherst Street gate, is a small grey building, containing three wards which will accommodate about thirty patients, an operating-room and surgery, besides a small dispensary, and rooms for the resident staff nurses. The variety of cases treated has been considerable, including electric burns, many fractures resulting from falls, tuberculosis among the Indians, measles among the Esquimaux, and pneumonia among many of the Midway people who arrived from the tropics during the cold weather.

Two births have been recorded on the Exposition register, one at the Indian Congress and the other at the Philippine Village. The young Indian, christened Pan Anna by Governor Roosevelt, is a pure-blooded Navajo, and her birth was conducted in the true Indian fashion. A nest of hay was placed near the center of the tent, over which was spread a sheep-skin, wool side down, and above this, from the ridge pole of the tent, hung a rope. No method of antisepsis was used, but, as the pains became severe, the mother assumed a squatting position over the hay nest, holding to the rope above her head. Back of her, with arms around her and making pressure over the abdomen, was an old squaw, the *accoucheuse* of the tribe. When the doctor arrived the os was well dilated, but the bag of waters had not ruptured. Soon after a severe pain ruptured the membrane, and during the following pain the child was born, the waters flowing into the skin above mentioned. The usual custom is not to cut the cord until after the placenta has been expressed.

Another feature of interest to people in general, and doctors in particular, is the infant incubator. To a doctor perhaps the most interesting part is their method of feeding the prematurely newborn. Some infants when first brought from the mother are incapable of suckling. They gag when milk is poured into the mouth and vomit from irritation when a nasal catheter is used. Dr. Coney, who is in charge of the babies, uses a nasal feeding spoon for these children. The spoon is made by bending the edges of an ordinary spoon to form a nozzle which will allow but one drop at a time to escape. One six-and-one-half-month-old baby was brought in when five days old, weighing two pounds, eight ounces, and having a temperature of 93.4° F. A five-minute bath at a temperature of 110° F. roused the child's body heat to 98° F. Mother's milk, containing one or two drops of brandy, was fed to the child by the nasal spoon and in three days it was able to suckle. It now weighs five pounds, two ounces, and is three weeks old.

The present Staff is composed of the following: Dr. Roswell Park, Director; Dr. Vertner Kenerson, Deputy Director; Drs. Alfred Zittle, Alex Allen and Edward C. Mann, Internes.

THE METHODS OF MEDICAL DIRECTORS OF INSURANCE COMPANIES.

To the Editor of the MEDICAL NEWS:

DEAR SIR: When I suggested to you the desirability of writing to the insurance companies asking the medical directors what course they proposed to pursue concerning the insurance of Christian Scientists, I warned you that the chances were against your receiving many answers to your letters. What I said was based upon my own experience, which I now beg leave to give in detail.

Being anxious to verify the oft-repeated assertion that Jews live longer than other persons, I wrote to a number of medical directors of important life insurance companies asking them for any information they might have concerning the comparative longevity of Jews and non-Jews. My recollection is that I received only four answers. In no other branch of commence is it customary to ignore polite letters asking reasonable questions, and the policy of so-doing appears to me to reflect upon the business capacity of the gentlemen who adopt this unusual procedure.

Two of the answers which did reach me throw some light upon the scientific attainments of those who pose as experts upon the

technical aspects of life insurance. My communication, addressed to the medical department of one of the great companies, was forwarded to a general agent, who favored me with the following ludicrous reply to a scientific question:

"I regret that we are unable to furnish you with any statistics relative to the longevity of Jews and non-Jews. The writer has recently seen a statement to the effect that a greater longevity does prevail among the Jews than the Gentiles; but is unable at this time to advise you where he got the information."

The second answer to which I have referred informed me that an insurance company could not ask an applicant about his religion, and on that ground statistics of Jewish longevity could not be furnished. Anybody who supposes that Judaism is merely a religion must be strangely ignorant both of history and of ethnology. Surely no religion, however old, can construct the Jewish face! Surely religion, unaided, could never have produced such marked "biostatic" phenomena as are found among Jews all over the world! Nevertheless, to the medical directors of some companies, all persons born in what was formerly Poland are Poles, and everyone born in Canada is a Canadian, whether a *habitant* or the son of Scotch parents. Unless my powers of observation are seriously at fault, the Polish Jew has very few ethnic characters in common with non-Jewish Poles, and the most important characters of Jews are identical, whether they were born in Russia, England or the United States. The "argument" which I occasionally hear, that "Poles are not classified by religion in death certificates," is worthy of the nursery. For practical purposes, Jews must be regarded either as a race or as a people, and any insurance company that wishes to collect statistics showing whether they are good risks or bad risks need only print the words "Race and Nationality" on its medical examination blank, and then give some simple instructions to its examiners. I am not acquainted with any Jew who is ashamed of his descent, and the number of Jews who would object to being asked an explicit question upon the subject by a life-insurance examiner must be extremely small. As a rule, however, the information will be given voluntarily in reply to the query named above.

Upon the subject of Jewish longevity, I have obtained some valuable facts from foreign companies; but these companies are not making streunous efforts to insure everybody who has one leg outside the grave; they are *not paying* gigantic commissions to agents; but they *are paying* more than $3.00 for medical examinations, even when the amount of the policy is less than one thousand pounds ($5,000). It is safe to say that they have no "lightning" examiners, who boast of their ability to make an examination in less than four minutes. Before leaving this aspect of the case, I should like to mention the following facts: One of the largest companies in the United States has now omitted chest expansion from its examination blank. Another company, not so old and smaller, has printed a table of thirty principal "causes of death," among which I find "apoplexy," "convulsions," and "dropsy." To the statistician, these so-called "causes"—in reality symptoms—are valueless. A third company has published a volume containing its history for the past fifty years, but I have not succeeded in seeing the book. I wrote to the home office asking if I might be allowed to look at a copy. A young gentleman then came to enquire for what purpose I wanted it. I told him. After the lapse of some weeks, he called again and kindly informed me that the book was not visible at present, because the official in Buffalo who owned it had had a fire at his residence! Apparently this copy was the only one obtainable at the time. But why should a work of this kind be published if it is to be kept from the gaze of persons who have some knowledge of vital statistics?

I venture to urge that the medical departments of some life-insurance companies need reforming somewhat badly. As far as business matters are concerned, every courteous letter ought, of course, to be answered. It should not be necessary to mention this. As to scientific subjects, the life-insurance director has a great deal to do with statistics and with questions of heredity—departments of knowledge which are not taught in medical colleges. I can assert without fear of contradiction by any competent person that physicians, as a rule, are not even familiar with the terminology used by statisticians and by those biologists who make a study of the problems of heredity. That the existing system of managing the medical part of some companies is very defective is shown by an article in the *Buffalo Medical Journal* for January of this year, the title of which is "The Importance of the Position of Medical Examiner for Life Insurance." The author is Dr. Frank M. Maloney of Rochester, N. Y. He says: "It is a sad commentary on the ability and honesty of our profession when one company divides its insurance into two classes, as an experiment, keeping and noting the record of those examined and those unexamined, to find that after a certain number of years the mortality of those unexamined was less than that of the examined. . . ."

Although I know nothing of medicine, I cannot refrain from asking how the medical department of the company to which Dr. Maloney refers has justified its existence.

As to Christian Scientists, it is quite obvious that if a man has no regular medical attendant,

or does not know when he last needed the services of a physician, or cannot give the name of the practitioner who last prescribed for him, that man ought to be rejected by all mutual life-insurance companies, for the very good reason that the acceptance of persons who cannot give this information is injurious to the interests of the policy holders.

I dissent from the expression "a good healthy Christian Scientist" in your editorial of June 1st. No doubt there are some "healers" who are physically healthy, and are merely charlatans of a pronounced type. But most Christian Scientists are mattoids, who are quite often the personification of *mens infirma in corpore infirmo.*

LAWRENCE IRWELL, M.A., B.C.L.

Buffalo, N. Y., July 5, 1901.

OUR LONDON LETTER.

(From Our Special Correspondent.)

LONDON, July 6, 1901.

THE REFORM OF THE ARMY MEDICAL SERVICE—APPOINTMENT OF A COMMITTEE OF EXPERTS—MR. BURDETT-COUTTS AND HIS ABORTIVE OBJECTION—SOME PERSONAL APPRECIATIONS—THE NEW CORONER FOR THE CITY OF LONDON.

IN the House of Commons on June 27th Mr. Brodrick, the Secretary of State for War, announced that a committee of experts had been appointed to consider a scheme drawn up by him for the future organization of the medical service of the Army. This Committee consists of Dr. Howard H. Tooth, physician to St. Bartholomew's Hospital; Mr. George H. Makins, surgeon to St. Thomas's Hospital; Mr. Alfred D. Fripp, assistant surgeon to Guy's Hospital; Sir Frederick Treves, formerly surgeon to the London Hospital; Professor Alexander Ogston, of Aberdeen, as representing Scotland; Lieutenant Colonel Keogh of the Royal Army Medical Corps as representing Ireland; Dr. E. C. Perry, physician to and medical superintendent of Guy's Hospital; Surgeon-General Hooper, President of the Medical Board, India Office; and two officers to be named by the Commander-in-Chief to represent the Army. The Secretary of the Committee will be Major H. E. R. James of the Royal Army Medical Corps, and the War Minister will himself officiate as Chairman. In reply to questions Mr. Brodrick stated that he did not propose that the deliberations of the Committee should be hurried as he wished to put the Corps on a permanently good footing. The irrepressible Mr. Burdett-Coutts, who takes everything relating to the medical service as his own special province, attempted to raise an objection to the inclusion of Sir Frederick Treves in the Committee and was promptly snuffed out by the Speaker who ruled that any comment on the names of the persons selected to act on the Committee would be out of order. Doubtless what Mr. Burdett-Coutts wished to do was to repeat a charge against Treves which is as meaningless as a parrot cry and as irritating by what Falstaff would call its "damnable iteration." When Treves and MacCormac returned laden with laurels from their three or four months' trip to South Africa, they were entertained at a big dinner at the Reform Club with Lord Rosebery in the Chair. At that time the devastating epidemic of typhoid fever at Bloemfontein, which brought such an avalanche of criticism on the medical service, had not broken out, and the Army Medical Corps had worked more efficiently than any other branch of the Army. Treves bore emphatic testimony to its good work, speaking of what he had actually seen. Naturally he said nothing about misfortunes which were then still in the womb of time. For this lack of the prophetic faculty Treves has been denounced with childish persistency by Burdett-Coutts as if he had borne false witness as to the state of things in South Africa.

The Committee is a fairly strong one, though the amateur war-surgeon element is perhaps too predominent. Treves himself is known to have views on the subject of army medical reform, for not long ago he gave them to the world in our leading monthly magazine, the *Nineteenth Century and After.* He was also a member of a committee of the British Medical Association appointed to draw up a scheme of reform, but he refused to sign the report on the ground that he did not approve of its suggestions. As the Committee had taken many of its principal suggestions from his article, they were naturally not a little surprised at this repudiation. It was clear, however, that Treves wished to cut himself adrift from them and paddle his own canoe, his motive obviously being to leave himself free to accept an invitation to act as adviser to the Government. Dr. Tooth—who is probably a great man, for has it not been said that the world knows nothing of its greatest men?—has, it may be surmised, been selected because he saw much of the typhoid epidemic and has thus become, almost *malgré lui,* an authority on war sanitation. Mr. Makins is an amiable man and a good surgeon who was lucky enough early in his career to find a protector in Sir William MacCormac; by clinging to the ample coat-tails of that star-spangled Knight of the Scalpel he has risen to a height of most respectable mediocrity where he is popular because he excites no envy. As applied to the medical profession the counsel of the Wise Man, "Beware when all men speak well of thee," may be taken to mean that a man who has no detractors is not thought to be worth disparagement. Mr. Fripp is a young man who has hitherto been the spoilt child of fortune. While in a provincial town doing duty for a general practitioner he was called in to heal a scion of royalty who had received a poisoned wound from Cupid's dart. So successfully did the surgeon minister both to the body and the mind of his illustrious patient that he became a favorite not only with the princeling, but with his exalted parents. When a year or two ago the Prince of

Wales—now *Die gratiâ* King and Defender of the Faith—suffered a fracture of his patella, the faithful Fripp was in attendance and helped MacCormac to do nothing—a method of treatment which they carried out with great skill. Then he went to the war, and while in South Africa contrived to keep the world at home fully informed as to his doings. Fripp may be trusted to go far, for, to paraphrase Pope's phrase about Arbuthnot, he knows his trade as well as his art. The mention of Arbuthnot, by the way, recalls the fact that Queen Anne's famous physician likewise owed to an accident his first start towards professional success. He happened to be passing when a Royal Duke broke his leg, and took at its turn the tide that led to fortune. Such accidents, however, can profit only those who deserve to be favorites of Fortune. Professor Ogston is a surgeon of the highest reputation. He went out to South Africa at his own expense and went about in the capacity of what his countryman Robert Burns described as "a chiel takin' notes." At the annual meeting of the British Medical Association, held in Portsmouth a few years ago, Ogston delivered an address which gave mortal offense by its outspoken frankness of criticism to the medical officers of the Army and Navy. He expressed the opinion that, owing partly to the want of opportunities of practice and partly to the cheese-paring policy of the Government which would not grant them leave to refurnish their knowledge and skill by post-graduate study, they were not up to the level of their brethren in civil life. He said nothing but what was true, but naturally the truth was unpalatable. Ogston's selection will probably be resented by the Army Medical Corps, but impartial outsiders who know the facts of the case regard him as the strongest man in the Committee. Lieutenant-Colonel Keogh is said to be a level-headed man, but such reputation as he has is purely departmental. Dr. Perry is an able man who has proved himself a first-rate administrator at Guy's Hospital; but he can have no personal knowledge of the special problems involved in the reform of the medical service of the Army. Surgeon-General Hooper's military experience has been gained wholly in connection with the Indian Medical Service which is an altogether distinct branch.

On the whole the Committee, if it might have been better, might have been a good deal worse. It is something to be thankful for that there is to be a Committee at all, for there appeared to be some reason to fear that the Secretary of State, whom no one could justly accuse of want of confidence in himself, would attempt the reform of the service without the help of any one. As it is he does not ask the Committee to draft a scheme, but to consider a scheme which he has evolved from his inner consciousness. It is said that the fundamental principle of his scheme is to have the medical supervision of the troops on home stations carried out by civilian practitioners at contract rates, and have a small medical corps for foreign service. If this is true, it is to be hoped that the experts may be able to convince him that the plan is unworkable. Civilians have no notion of military discipline and do not care to be instructed in its mysteries. On the other hand, no man would consent to expatriation for the best years of his life—and this would be the fate of an officer entering a corps employed only for foreign service—without a much more liberal scale of pay than the Government is likely to offer.

Dr. F. J. Waldo has just been elected Coroner for the City of London. He is a graduate of Cambridge and a pupil of Koch. As Medical Officer for the Borough of Southwark he was strenuous in his efforts for the hygienic reform of bakehouses and for the sanitary control of night-shelters. In connection with the latter point, he incurred the anathemas of the Salvation Army by his unsparing exposure of their neglect, not only of sanitary requirements, but of ordinary cleanliness. It is noteworthy that among eighteen candidates for the coronership the three selected were all members of the medical profession. Yet till Thomas Wakley, the founder and first editor of the *Lancet*, won by popular suffrage the post of Coroner for Middlesex, that office was regarded as an appanage of the legal profession.

ELEMENTS OF TYPHOID SERUM—TUBERCULOUS CEREBELLAR TUMOR—OLD PLEURISY AND EMPYEMA—INTENSIVE SERUMTHERAPY IN DIPHTHERIA.

M. WIDAL, at the Société Médicale des Hôpitaux, June 14, 1901, read a paper on the existence of *sensibilisatrice* in the blood-serum of typhoid patients, and said that the researches of M. Bordet have shown that the bactericide and cytolytic properties of the specific serums are due to the combination of two substances or elements. The first of these factors is called *alexine;* it exists in the serum of normal adults and may be destroyed by a temperature of 56° C., and acts itself for the destruction of the germs. The other substance is *sensibilisatrice;* it is alone a specific product, occurs in the blood of vaccinated individuals and serves to promote the sensitiveness of the germs to alexine. For establishing the existence of this element, sensibilisatrice in antimicrobe serums, M. Bordet made sole use of this peculiar property which it possesses of causing the organisms to absorb the destructive alexine. Unlike alexine, he found that sensibiliatrice is not destroyed by a temperature of 56° C. Now, if one works up together a normal serum, which has never been heated, with an isotonic emulsion of typhoid fever bacilli and with a serum of vaccinated guinea-pigs, previously raised to 56° C., the bacilli thus rendered more sensitive will absorb the alexine or destruc-

tive element which will disappear from the medium. If now to the above mixture, after a lapse of five hours, one adds a certain quantity of red blood-cells rendered sensitive by having been acted upon by a specific serum, similarly heated to 56° C., hemolysis will not occur. The explanation of this phenomenon is that the alexine of the serum, which in the first mixture had not been heated and which would determine the hemolysis, has been entirely and fixedly absorbed by the typhoid bacilli in the first experiment. If, on the contrary, this first mixture had been made with a non-typhoid serum, consequently not containing any specific sensibilisatrice, the alexine would not have been fixed by the non-sensitive bacilli and left free would have been active in producing the hemolysis of the red blood-cells. M. Bordet and M. Gengou have found that the serum from two convalescents from typhoid fever hindered hemolysis and therefore contained sensibilisatrice. M. Widal with M. Le Sourd have endeavored to make the same experiments with typhoid patients during the invasion and course of the disease. In ten dothienterics they found the phenomenon in the course of the disease, in three as early as the ninth day, but in none was it possible to establish the presence of the substance at any earlier stage of the malady. The control experiments which they carried out with the blood-serum of forty patients afflicted with tuberculosis, erysipelas, gastric disorders, angina or other cardiac affections have given only negative results. The bacilli typhosi in these tests did not fix the alexine and the red blood-cells underwent hemolysis.

M. BERGOUIGNON reported in the name of M. HUCHARD and his own the case of a young woman, thirty years old, who manifested during the course of a pulmonary tuberculosis all the symptoms of cerebellar tumor, occipital headache, bilious vomiting, vertigo, titubation, etc., and who died in coma. The autopsy confirmed the diagnosis by revealing a large tuberculous mass in the right cerebellar hemisphere and in both cerebral hemispheres. The pia mater was covered by numberless small tubercular nodes and the two lungs were nearly destroyed.

M. PIERRE MERKLEN in the discussion said that the syndrome of cerebellar disease is often reduced to cephalalgia, but the characteristics of it are almost pathognomonic. Its seat is always occipital and its intensity is always augmented by the least effort, because exertion determines an increase in the intracranial pressure and adds to the hydrops of the ventricles, which is originated by the venastasis in the veins of Galen from the pressure of the tumor. The mechanism of this pathogenesis was well shown by an interesting case under his care some years ago. The patient was a young man who suffered from unendurable headache, occipital and increased by the slightest exertion. Its steady increase suggested the wisdom of a palliative trephining of the skull. The pain thereafter grew less, but the scar soon began to bulge and from it was aspirated large quantities of cerebrospinal fluid. Finally, the autopsy showed a cerebral hernia, containing the posterior horn of the lateral ventricle, a large hydrops of both lateral ventricles and a tuberculous tumor of the left cerebellar hemisphere, which, by pressure on the veins of Galen, had caused them to dilate and the lateral ventricles to fill. The same clinical history obtained in another case, but at the operation a cyst was evacuated and relief obtained.

M. TRIBOULET disputed the statement that cephalalgia is always a sign of cerebellar tumor, for he had a child among his patients, who never had any headache, but suffered from persistently recurrent vomiting and life was ended by a series of apoplectiform seizures. At the autopsy a cerebellar tumor was found.

M. GAILLARD found a hydatid cerebellar cyst in a man who had only severe headache, provoked to crises by the least exertion.

M. FAISANS exhibited a medical curiosity in a specimen of the thoracic viscera with the pleura much thickened and converted into a veritable shell, cartilaginous in some places and osseous in many others, containing in its cavity a thick turbid fluid in which all cellular elements had long since ceased to exist. This pleurisy dated back forty years and the patient had died after an operation, thoracentesis, rendered necessary by the displacement of the heart. Later in life the patient had also developed cirrhosis.

M. RENDU asserted that on general principles it is advisable to interfere at an early date with all recent empyemata, but it is always bad practice to do so when the pus is dead, free of all cellular matter and abundant only in cholesterine.

M. BARBIER pronounced the recent epidemic of diphtheria in Paris as unusually severe in that the false membranes not only are extensive, but also are inclined to increase notwithstanding all efforts and serumtherapy to the contrary. Furthermore, after an apparent disappearance, they seemed inclined to recur and to be associated with various disquieting symptoms. Consequently he has been practising what should be called an intensive serumtherapy, with M. Lobligeois, consisting in repeated injections of serum just as often as the indications called for, even until the patient had received 80, 100 or even 140 cubic centimeters of the remedy. A very special indication for this vigorous treatment is the existence of a tracheobronchitic complication. Further, in order to prevent diphtheritic paralysis, it is necessary to make the injections at the very first sign of the symptoms which always forerun paralysis.

Gonorrheal Arthritis.—Among the many remedies that have been tried in this disease, Toupet, Bourdillon, and others find that calomel injected into the muscles about the joint is as effective as any. They inject gm. 0.03 (gr. ½) every two to four days, the slight pain not causing any complaint.—M. THOMAS in *Le Mois Thérapeutique*, June 30, 1901.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF RUSH COLLEGE.

Regular Monthly Meeting, Held in Chicago, April 1, 1901.

Mediastinal Tumor.—Prof. Frank Billings presented this paper. The patient John J., age thirty-nine years, married, a laborer, presented himself January 23, 1901. The family history was negative. Previous health was good during his whole life, excepting an attack of bilious fever when twelve years of age. He uses alcoholic drinks very moderately; uses tobacco moderately, and denies venereal disease. A year and a half ago the present illness began with sharp lacinating pain in the right upper chest. This continued steadily, growing gradually worse until about three months ago, when he commenced to have a sharp ache in the left upper chest. This was aggravated by exertion and was especially bad at night. It was accompanied by radiating pain in the left shoulder and down the inner side of the arm to the elbow. The pain is worse when lying down and upon first moving about in the morning, but grows somewhat better after a little exercise. He has a dry cough aggravated by exercise, and the dyspnea of exertion. The voice has never been changed in quality. The appetite is capricious but digestion fairly good. The bowels are constipated. Patient is six feet in height, weight 135 pounds, a loss of 35 to 40 pounds from the full normal weight. The skin is sallow and muddy. The general appearance is one of cachexia. The eyes are negative. The larynx is negative. The superficial veins in the left pectoral region are dilated. Expansion of the chest is limited on both sides and is apparently due to want of muscular power. The respirations are rather rapid and shallow. The apex beat of the heart is visible and palpable in the sixth interspace in the nipple line. Dulness extends from the right sternal border at the top of the second rib to one centimeter outside the left nipple and upward on the left side to the third rib. No throbbing of the chest can be felt. At the apex of the heart a soft systolic murmur is transmitted downward into the seventh interspace and in the axillary line. No murmurs are heard at the base of the heart nor behind. The pulmonic and aortic second sounds are equal and not accentuated. The radial pulses are equal and synchronous. The carotids are equal and synchronous. The pulse is 96 per minute and occasionally intermits. The lungs are negative. The abdominal organs are negative. The urine normal chemically and microscopically. The blood shows 4,200,000 red cells, 70 per cent. of hemaglobin and 8,500 white cells.

This patient has been in the Presbyterian Hospital since January 26th and many examinations have confirmed the findings named above. Recently the radial pulses have been unequal, the left the smaller when the patient is sitting or standing, but they appear equal when he is recumbent. With rest in bed he has become more comfortable until now he no longer suffers from pain of any importance in the chest. The physical findings are, however, the same and an X ray photo shows a mass in the mediastinum just above the base of the heart. The diagnosis of mediastinal tumor is based upon the fact that the patient denies venereal disease, has a family of healthy children, his wife has never miscarried, the disease has been slowly progressive associated with loss of considerable weight accompanied with a cachexia. Furthermore, by the fact that in spite of the pressure being great enough to interfere with the circulation in the vein and at a point which must be near the transverse arch of the aorta and therefore near the recurrent laryngeal nerve and blood-vessels of the left side, it has not produced a change in the pupils or larynx or pulse which one would expect to find in an aneurism of the same region. On the other hand, the patient has improved with rest and with moderately large doses of iodide so that there is a possibility of aneurism and the diagnosis of mediastinal tumor is therefore tentative.

Malignant Mediastinal Tumor.—Drs. E. Fletcher Ingals and Otto T. Freer presented the history and pathological specimen of a case of this affection occurring in a man about thirty-five years of age. The first symptoms, consisting of coryza and tickling sensation in the throat, had begun about four months before he came under observation. Dyspnea began about a month later and had steadily increased. At the end of two months there had been some swelling and congestion of the face, and distention of the superficial veins were noted, but there had been no pain. When first seen the patient was strong and well nourished, but the cough was very troublesome and the dyspnea alarming if he lay down for a few minutes. There was dulness on the front of the chest over an area extending from the clavicles to the lower edge of the ribs and laterally about three inches each side of the sternum, with flatness over the lower part of the right chest. The fluoroscope revealed a dark shadow nearly corresponding to, though somewhat larger than, the area of dulness. The respiratory sounds were absent over a large part of the dull area and lower part of the right side but were nearly normal elsewhere. Tracheal râles indicated compression of this tube. The superficial thoracic and abdominal veins were moderately enlarged and upon stripping the superficial epigastric veins the blood was seen to be flowing downward because of obstruction of the superior vena cava. There were a number of slightly enlarged inguinal and cervical glands and the left vocal cord was paralyzed in the cadaveric position. The patient grew steadily worse and died in about two weeks.

Autopsy.—Postmortem revealed a larger anterior mediastinal sarcoma corresponding closely in size to the clinical findings. There were very slight changes within the abdominal cavity. There was a large collection of serum in the right pleura, extensive adhesions of the left pleura and the heart and larger blood vessels together with the trachea were much involved by the tumor mass. The very interesting pathological changes were demonstrated which explained the symptoms that had been observed before death.

Calculi.—Dr. Arthur Dean Bevan presented specimens of salivary, hepatic, pancreatic, renal, cystic calculi and reviewed the points in the etiology, pathology and natural history common to all of them. He also briefly reported the cases from which the specimens had been obtained and stated that all true stones consisted of two sustances of different origin: One, the frame-work of organic material derived from the mucosa of the duct or reservoir in which the stone was formed; the second, the crystallizable substances derived from the secretion of the gland in connection with this duct. He believed that the essential cause of true stone formation in any position was a catarrhal inflammation of the mucosa of mycotic origin.

Salivary Calculus.—In the case of salivary stones in addition to this essential cause, *i. e.*, mycotic infection, there was occasionally found as a nucleus, a foreign body which had worked itself into the ducts of the salivary gland. The germs producing a catarrhal inflammation of the mucosa which led to the development of salivary calculi gained access to the mucosa probably from the mouth through an ascending inflammation. The finding of leptothrix and other germ forms by Klebs and Gallippe in salivary calculi seemed to demonstrate this fact. One could not exclude, however, the possibility of such germs reaching the salivary glands and ducts through the circulation.

Gall-Stones.—In connection with gall-stones, the same etiological factors are present. The germs producing the essential catarrhal inflammation reached the mucosa of the bile-tract by an ascending inflammation from the intestines in some cases; in others probably through the blood carried to the liver. It is difficult to state which route is the more common as the germs usually found in gall-stones, the colon bacillus and the bacillus of typhoid, might reach the bile-tracts by either route. Foreign bodies are occasionally, but very rarely here, the nuclei of stone.

Pancreatic Calculus.—In connection with pancreatic stone, Dr. Bevan stated that the etiological factors were practically the same as in gall-stone formation. He called attention to the difficulty of diagnosing pancreatic stone and to the probability that it was more common than we have heretofore believed, also that it was probably an important factor in acute pancreatitis and fat-necrosis. The development of the surgery of the pancreas within the last few years makes us hopeful that in the near future we shall be able to diagnose and operate successfully for pancreatic calculi. In 1885, when Charles T. Parkes first suggested and planned choledochotomy, it seemed to the surgeons of that day as difficult an undertaking as the removal of a stone from the pancreatic duct seems to us to-day and yet choledochotomy soon earned for itself the position of one of the most successful and brilliant of surgical achievements.

Urinary Calculi.—In demonstrating a number of calculi from the urinary tract, he stated that we had here, probably, again the same etiological moments, viz., a catarrhal inflammation of the mucosa of mycotic origin. There could be no question that the germs producing this inflammation might reach the mucosa either by ascending the urinary tract or might be brought to the kidney or bladder by the blood. He believed the most common germ form here was the gonococcus, which represented the first route, and the bacillus of typhoid and the colon bacillus both probably representing the second.

The natural history and symptom complex are very much the same in all forms of calculi. They may remain for years innocuous without giving evidence of their existence; if they do give evidence of their existence, it is either because mechanically from change of position or increase in size, they interfere with the patency of the duct or reach a point in the duct too small for their accommodation, as in the passage of a stone through the common duct or a stone through the ureter; or more frequently, the cause of symptoms was the occurrence of a fresh infection of the mucosa—this infection favored by the presence of the calculus. The X ray is of great value in determining the presence of urinary calculi whether in the kidney, ureter, bladder or prostate. This means of diagnosing has not as yet been satisfactory in determining the presence of gall-stones excepting in a limited number of cases. Within the last few years much brilliant work has been done in kidney-stone surgery, thanks to this means of diagnosis.

HARVARD MEDICAL SOCIETY OF NEW YORK CITY.

Stated Meeting, Held April 27, 1901.

The Vice-President, William B. Coley, M.D., in the Chair.

Acute Intestinal Obstruction Following Operations for Appendicitis.—This paper was read by Dr. Arthur L. Fiske.

It will appear in a subsequent issue of the MEDICAL NEWS.

The discussion was opened by Dr. Charles L. Gibson, who said that appendiceal troubles and

operations for appendicitis are a common cause of intestinal obstruction. The most frequent cause of acute obstruction of the intestines is the formation of bands beneath which the intestine becomes nipped. Out of one thousand cases of intestinal obstruction collected some time ago by Dr. Gibson, nearly 200 were due to adhesive bands. The frequency with which intestinal obstruction is located in the right iliac region is a sure sign that the adhesions and other pathological conditions which cause the obstruction are due to an antecedent appendicitis. In a certain number of cases, stricture of the rectum is also due to the inflammatory conditions consequent upon appendiceal affections. The inflammatory products gravitate down into the pelvis, especially when the situation of the appendix has been such as to favor this gravitation. The connective tissue formed by the eventual organization of the inflammatory tissue has a tendency to contract, which accounts for its production of intestinal obstruction and also of the narrowing of the lumen of the rectum.

Appendix as Constricting Band.—Dr. Gibson has seen the appendix itself as a constricting band in certain cases of intestinal obstruction and in the literature of the subject this portion of the intestine is mentioned not infrequently as the source of the obstruction. When the tip of the appendix becomes inflamed it is liable to contract attachments to surrounding structures and these prove the source of obstruction later on, when the acute inflammatory condition subsides.

Prophylaxis of Subsequent Intestinal Obstruction.—After operations upon the intestines in which there has been considerable inflammatory exudate thrown out it is advisable to have the function of the intestine recommence as soon as possible after the surgical intervention. For this purpose early free catharsis seems especially indicated. McCosh's injection of concentrated salt solution commends itself as an excellent remedial measure for this purpose. It is Dr. Gibson's custom to inject an ounce of Epsom salts dissolved in as little water as possible just beyond the part of the bowel that has been operated upon. In cases of appendicitis the injection is made through the stump of the appendix. As soon as the patient is able to take medicine by the mouth, calomel is given. The custom of injecting the salt solution in the manner described is a source of great comfort to the surgeon, who realizes that the restoration of the function of the intestine is practically immediate. The habit of doing so also saves the patient a good deal of inconvenience, and improvement after nutrition comes sooner since the patient's stomach is not disturbed by purgative medicines.

Decrease of Intestinal Obstruction.—Dr. John B. Walker said that intestinal obstruction has become more infrequent of late years. There is no doubt that the more careful diagnosis and surgical care of appendicitis has something to do with this. Post-operative intestinal obstruction is rarer than it was, because operations are usually aseptic and much more care is taken not to leave raw surfaces that may prove the origin of adhesions. It must not be forgotten that sometimes intestinal obstruction in its initial stage, before the symptoms have become too severe, will yield to high enemata.

Pressure as Cause of Adhesions.—In one case in Dr. Walker's recent experience the symptoms of intestinal obstruction developed about six days after an operation for appendicitis. There had been a large abscess and a considerable amount of gauze was used for packing. The intestines were thus pressed tightly together and this was doubtless the cause for the formation of adhesions that led to the knuckling of the intestines and consequent occlusion of the canal. The symptoms were not of the severest type and vomiting did not occur, but there was almost constant hiccoughing. Reopening of the abdomen showed that adhesions had been formed between the stump of the appendix and the knuckle of intestine. The adhesive bands that form in these cases are more often the cause of intestinal obstruction than any other pathological condition.

Adhesive Bands after Appendiceal Operations.—Dr. Edward M. Foote said that he had seen a series of autopsies after death from delayed appendix operations, but had never seen any adhesions formed in the appendiceal region. Death in these cases was due to sepsis. Mechanical elements, such as the presence and pressure of gauze, undoubtedly play an important rôle in bringing about the development of adhesions. In recent years, when the technic of appendiceal operations has been made more perfect, the development of such adhesions is much less frequent than it used to be. Covering in all exposed surfaces and not allowing the stump of the appendix itself to remain as a raw surface from which the oozing lymph may easily lead to the formation of adhesions are important precautions.

Acute Obstruction with Gangrene.—Dr. William B. Coley said that he has not seen any cases of intestinal obstruction after appendicitis except this recent one. A boy of ten was operated upon for appendicitis and made a perfectly good recovery. Six months after the appendicitis operation he had an acute attack of intestinal obstruction. He was in the country at the time and had to be operated on under somewhat unfavorable circumstances. The operation was delayed until it was scarcely more than a last resort and the patient's condition was almost hopeless. Three and a half feet of the intestine were found to be gangrenous. The patient's condition was so bad that it was feared that the continuance of the anesthesia and of the exposure of the intestine for a length of time sufficient to perform intestinal anastomosis would surely prove fatal. Both ends of the intestine resected were

brought out to the median line and secured there. The patient made a reasonably good recovery. The end of the intestine from which the intestinal contents came was rather high up in the ileum. As a consequence the patient's nutrition suffered very severely.

Resection and Anastomosis.—Three and one half years after the original enterostomy the patient came under Dr. Coley's treatment in a state of severe emaciation as the result of his intestinal fistula. A radical operation was done, both ends of intestine being resected and the two portions of the severed gut brought together by means of a Murphy button. The operation proved a perfect success, but, though the patient remained for four weeks under careful observation in the hospital and the button was faithfully looked for at home, no trace of it was ever found. Just what has become of it remains a mystery. The patient gained twenty-eight pounds in six weeks and is now in excellent condition and without a symptom from his surgical experience. Dr. Coley is of the opinion that intestinal obstruction will occur less and less frequently, as appendicitis is treated better and earlier, and that post-operative obstruction will be lessened by the thorough removal of all inflammatory products at the time of the operation, that is, as far as is possible, and by taking due precautions not to leave any raw surfaces exposed.

Old Appendicitis in Intestinal Obstruction.—Dr. Arthur L. Fiske said in closing the discussion that Treves thinks most intestinal obstruction is due to bands of connective tissue formed as the result of chronic inflammatory conditions in the neighborhood of the appendix. Other authorities agree with Treves in this matter and there seems no reason to doubt that the better treatment of appendicitis in our day will lead to a reduction in the number of cases of intestinal obstruction that occur. Even when intestinal obstruction does occur after operations for appendicitis, the condition cannot always be considered as due to the operation. It might very well have developed in the ordinary course of the inflammatory process and the operation may indeed have delayed their formation, or rendered their effect upon the intestine less serious. In order to avoid the formation of adhesions at the time of an appendiceal or other intestinal operation, the use of salines in the bowel seems advantageous. Peristalsis is stimulated at once and the intestinal adhesions are broken up early or avoided entirely.

High Enemata in Intestinal Obstruction.—In Dr. Fiske's opinion the use of high enemata when symptoms of real intestinal obstruction have developed is never of avail. In three of his cases they were faithfully employed, but did absolutely no good. In very bad cases they always involve a certain amount of danger. In other cases they mean the loss of precious time. Time is the main element in the prognosis of intestinal obstruction. Changes in the bowel rapidly take place. Once complete obstruction has been established the conditions for good surgery very soon disappear. It is a relic of medical tradition to use high enemata, but it really seems in most cases scarcely wise to make the delay for this unavailing purpose. It is doubtful if the liquid of the high enema can ever be forced beyond the ileocecal valve. In infants, in whose elastic tissues the attempt should succeed if anywhere, Dr. Fiske has often tried to force water by pressure beyond the ileocecal valve, in cases of intestinal invagination, but has always failed. Cases reported in literature show that where pressure is employed rupture of the bowel is apt to take place. Once the diagnosis of intestinal obstruction is made, operation should be done as soon as possible. Where the operation is performed early, the prognosis is reasonably good. Not more than 25 per cent. of patients operated on during the first twenty-four hours of their symptoms of acute intestinal obstruction will be lost. After the first twenty-four hours the mortality doubles.

Post-Appendicitic Obstruction.—Intestinal obstruction which develops after operations for appendicitis seems to be due to collapse of the abscess wall and consequent kinking of the intestine which forms part of the wall. In these cases, as the result of agglutinative processes, owing to the new mechanical conditions established, there is apt to be a sharp angle made in a fold of intestine, and this leads to congestion, stoppage of peristalsis and to complete obstruction. With the first symptoms of intestinal obstruction, careful watch should be kept of the patient, and if the symptoms increase the abdomen should be opened. If this procedure were followed with confidence in every case, the mortality of the operation by intestinal obstruction would be greatly lowered. The bother so far has been that operation for intestinal obstruction is looked upon as a last resort, somewhat as a forlorn hope. This is a legacy from the days when aseptic surgery of the abdominal cavity was unknown, and when a great majority of patients on whom laparotomy was done necessarily perished. The condition that exists and that causes the intestinal obstruction is a very simple one. As a rule, only thin, fibrous bands of adhesions are found, but these are sufficient to bind the intestine down at an acute angle that occludes its lumen. These can be very easily broken up and the lumen re-established after laparotomy.

The Harvard Medical School.—Dr. Edward M. Foote presented a series of statistical details showing the comparative standards of the prominent medical colleges of the country. This table makes it clear that Harvard is retaining her position of pre-eminence among the medical schools of the country in the best sense of that term. Harvard has more profes-

sors and instructors in her medical department, devotes more time to laboratory and clinical work, requires a higher standard for admission to her medical school and demands a more thorough knowledge of medicine for graduation after her course is completed.

CHICAGO PATHOLOGICAL SOCIETY.

Stated Meeting, Held May 13, 1901.

The President, L. Hektoen, M.D., in the chair.

The Cellular Changes in Tuberculous Meningitis.—Dr. I. B. Diamond presented a paper on this subject. Plasma, lymphoid and phagocytic cells form the greater portion of the cell-infiltrations in the vascular and extravascular areas of the leptomeninx in acute tuberculous meningitis. The plasma and lymphoid cells emigrate largely from the lymph-spaces of the arterial adventitia and from the finer capillaries. They proliferate largely by indirect division, a certain number, however, are derived from lymphoid cells. There are two kinds of phagocytes (1) those which proliferate from the endothelial lining of the capillaries and lymph-spaces, and (2) those from the subendothelial intimal connective tissue. The most important of the vascular changes—the tuberculous endarteritis—develops in the following manner: Plasma and lymphoid cells accumulate underneath the endothelium of the intima; later the subendothelial intimal connective tissue cells are found mixed with the former. They proliferate next to the elastic coat, are to a certain degree phagocytic and resemble epithelial cells. They also run together and form giant cells and in this manner characteristic intimal tubercles develop. Changes of the endothelial lining of the arteries occur later, especially when there is caseation or hyaline degeneration of the collection underneath. Of interest is the great production of plasma cells which is analogous to the cell changes described by Councilman in acute interstitial nephritis, while on the other hand, the production of phagocytic cells is analogous to the cell changes described by Mallory as occurring in typhoid fever.

Bubonic Plague.—Dr. Lewellys F. Barker presented gross and microscopic specimens of the buboes and internal organs removed from Chinese dead of plague, in San Francisco. The demonstration was accompanied by a brief description of the pathology and pathogenesis of bubonic plague. In the bubonic form of the disease the lesions in the lymph-glands and surrounding tissues—edema, hemorrhage and necrosis—are very characteristic. The changes in the spleen are more marked in the septicemic form than in the bubonic form. The specimen of spleen under the microscope showed extensive necrosis of the splenic framework and pulp, with wandering in of polymorphonuclear leucocytes. Primary plague pneumonia is distinguished from aspiration pneumonia and from embolic pneumonia occurring as complications of plague. The enormous number of bacilli present, the abundance of blood in the exudate, and the small part played by fibrin, are interesting features. The question of portal of entry was discussed in connection with the various clinical types, and an effort was made to explain the fact that local lesions in the skin and mucous membranes and lymphangitis are rarely present, the first outspoken lesions occurring in the nearest packet of lymph-glands.

Atresia of Follicles.—Dr. Leo Loeb demonstrated microscopic section showing the difference between the atresia of follicles in different stages of maturity; also microscopic sections of two ovaries of a guinea-pig in which all follicles presented the picture of hypertrophy of the epithelium and in which the atresia without exception started by the ingrowth of connective tissue and capillaries into the follicular epithelium. Two slides were demonstrated showing follicles in the process of atresia, each one of which contained two ova. In one of these two follicles both eggs showed progressive changes; in the other follicle, one ovum was unchanged and well preserved; the other ovum was segmented. In a third atretic follicle, of which a slide was shown, in which three ova were present, two of these were unchanged, the third ovum had undergone certain changes, the exact nature of which could not with certainty be determined. Another specimen showed a structure resembling very much a small corpus luteum, in the center of which, however, two successive sections demonstrated the presence of an ovum. At present it must be left undecided, if in this case the ovum of a ruptured follicle was retained and a corpus inteum had formed around it, or if under certain conditions a follicle which had not ruptured previously might in the stage of atresia give rise through hypertrophy to a structure similar to a small corpus luteum.

Perforation of Stomach by Gastrolith.—Dr. Maximilian Herzog presented a gastrolith composed of persimmon seeds which had caused perforation of the stomach and death in a three-year-old boy in the practice of Dr. Cargile of Bentonville, Ark.

BOOK REVIEWS.

ORAL SURGERY. A Text-Book on General Medicine and Surgery as Applied to Dentistry. By STEWART LE ROY MCCURDY, A.M., M.D., Author of "Manual of Orthopedic Surgery"; Professor of Anatomy and Surgery, Pittsburg Dental College, Surgeon P. C. C. and St. L. R. R., etc. By the Calumet Publishing Co., Pittsburg, Pa.

IN looking through this book we have labored

long and faithfully to find something worthy of commendation, but our efforts have been unrewarded. It may be that the volume bears concealed somewhere between its flaming covers a gem that has eluded our search; if so, we apologize most sincerely, but the very difficulty of the undertaking stimulated us in our attempt to unearth some point on which we might hang a little word of praise and we were honestly grieved to find our good intentions frustrated at every turn. It is all too apparent that the book is one of a class that is rapidly increasing in these days, when teaching positions are easy to obtain and unfortunate students are morally coerced into buying a rubbishy compilation masquerading as a text-book simply because it bears on the title page the name of one of the faculty. The present instance offers a most striking example of the deplorable results to which the *furor scribendi* may lead, and the author cannot even justify himself, as did a witty writer of a former century, by saying:

"Ce livre n est pas long, on le lit dans une heure,
"La plus courte folie est toujours la meilleure."

for he is responsible for over 350 pages of bad writing, bad printing and bad illustration.

A TREATISE ON APPENDICITIS. By GEORGE RYERSON FOWLER, M.D., Professor of Surgery in the New York Polyclinic; Surgeon to the Methodist-Episcopal Hospital, etc. Second Edition, Revised and Enlarged. J. B. Lippincott Company, Philadelphia and London.

APPENDICITIS, ITS PATHOLOGY AND SURGERY. By CHARLES BARRETT LOCKWOOD, F.R.C.S., Assistant Surgeon and Lecturer on Descriptive and Surgical Anatomy in St. Bartholomew's Hospital, etc. The Macmillan Company, New York.

INFLAMMATION of the appendix and surrounding structures has now become one of the commonest ailments the surgeon is called upon to treat and each year the statistics are piling up an increasing rate of morbidity from this cause. The almost meteor-like development of this condition is quite unparalleled in the history of medicine and no other disease has ever sprung to so prominent a place in such a short space of time. The study of the subject is fast verging into a specialty and the appearance in quick succession of numerous monographs is a certain index of the importance it is assuming. Whether we attribute the greater number of cases seen to-day simply to our better understanding of the lesion and, consequently, more accurate diagnosis, or hold with those who contend that, owing to hereditary, developmental and other obscure reasons, the race has actually become more susceptible, it is very evident that no physician is to-day competent to practice who has not given this subject more than passing attention.

The two volumes before us differ rather more radically than is apparent from their titles and, while both are of a very high order of merit and equally deserve the gratitude of the profession as adding to our knowledge in a field where much is still uncertain, we think that the American author will be found more generally useful to the average practitioner. Dr. Fowler's book, already in its second edition, is eminently practical and is full of information, particularly as to diagnosis and treatment, that will be of utmost value even to the accomplished surgeon. The elevated head-and-trunk position, which, we believe, is original with the author, is but one of many similar expedients described by him. It consists in raising the head of the bed twelve to sixteen inches, the patient being kept from slipping down by a pillow tied in place beneath the flexed knees. The object of the maneuver is to favor the gravitation of septic material away from the dangerous areas of absorption in the peritoneum, while the nausea and vomiting also are materially decreased and normal peristalsis favored.

Lockwood approaches the subject rather more as a pathologist and gives the clinical history, the operation and morbid anatomy, the morbid histology and a brief commentary on 83 cases that have come under his observation. Chapters on clinical symptoms, indications for operation, the technic of its performance, and after-treatment are added, but are less complete than in the American book. The nomenclature of the disease has already given rise to many wordy battles and the author enters the lists with a mild but still comprehensive criticism of most of the terms in common use, such as "relapsing," "recurrent," "suppurative," "perforative," and "gangrenous appendicitis," "appendicular colic," "perityphlitis," used as a synonym for appendicitis, etc., which in one sense is perfectly just since it is true that these designations have a purely clinical value and do not indicate definite pathological conditions, for many kinds of appendicitis may end in perforation or relapse, and appendicular colic probably never occurs without some histological lesion, etc. But these terms have been generally accepted by the profession and convey clear impressions to most of us, while the author's proposed substitutes, such as "appendicitis with ulceration of the mucosa and bacterial invasion," "appendicitis with ulceration of the mucosa and perforation," although they correctly define the pathological condition existing, are quite too cumbersome for ordinary use. About fifty microphotographs of sections of appendices are used to illustrate the text, but, while some of them are admirable, for the most part, as is usually the case with such reproductions, they are far less instructive than well-made drawings would be.

We hope that the differences of general scope existing between these two excellent works have been to some extent indicated; both are good, but for the man with a limited library Dr. Fowler's book will undoubtedly prove more satisfactory, while those especially interested will find much that is valuable and worthy of consideration in the work of his English colleague.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXIX. NEW YORK, SATURDAY, JULY 27, 1901. NO. 4.

ORIGINAL ARTICLES.

AN IMPROVED METHOD OF TREATING HIGH-SEATED CANCERS OF THE RECTUM.

BY ROBERT F. WEIR, M.D., (HON.) F.R.C.S. ENG., C.F.S.C. PARIS,

OF NEW YORK;

PROFESSOR OF SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY; PRESIDENT OF THE NEW YORK ACADEMY OF MEDICINE.

MANY will agree with me, I fancy, in considering the Kraske operation a very unsatisfactory one for the removal of high-seated cancers of the rectum. In addition to the depth of the wound, the more or less jagged invasion of the peritoneal cavity, the possible difficulty of satisfactorily drawing down the upper portion of the bowel, and, finally, the trouble that is involved in the proper suturing of the preserved portion of the rectum to the proximal end, all render it, with its annoying hemorrhage, an operation that is often in my judgment and experience troublesome and devoid of surgical neatness and precision. It is true that within four to five inches from the anus the affected part of the bowel within the area can be easily reached and removed and a fairly satisfactory sacral artificial anus created if the anus is involved. But if the anus and, say, two inches of that end of the rectum can be saved, a point which is of great importance to the subsequent comfort of the patient, which means a tumor at least three inches from the surface and to do which the bowel above must be liberated and brought down, then the foregoing objection applied to the surgical procedure in vogue must be taken strongly into consideration. They apply as well to the methods of approach from behind as in Kraske, or from the front (by the vagina) as has been recently advised. The latter I have not essayed, but an experience of over 20 cases of Kraske resection, 9 of which were followed by an attempt at union of the divided rectal ends, has markedly impressed me with the desirability of attacking high-lying cancer of the rectum in a somewhat different method.

Last year, *i.e.*, in January, 1900, I ventured to practise such an extirpation after the plan that Maunsell (then of New Zealand) had advised.[1] His suggestion, as you may remember, was, to open the abdomen above the pubis, separate the peritoneum from the bowel largely, and then to pass a loop of tape by a long mattress needle from the opened pelvis through the rectum and out the previously enlarged anus. By this he proposed to pull down the neoplasm loosened by its peritoneal divisions and by some additional blunt dissection and the finger, so that it would appear at the anus, everting the lower part of the rectum as it protruded. If the protrusion was accomplished, and to do this it might be necessary to acquire more room by freely dividing the anus back to the coccyx, then the tumor was removed and two ends of the bowel now, so to speak, out into the cold world, were easily connected with sutures and then replaced, the final step being the suturing of the divided peritoneum. This was a finely conceived operation but it did not work with me in my trial of it, the hitch being that the tumor would not pass through the divided anus and that the forcible traction enlarged the tape openings into the bowel so much that escape of its contents was possible. I therefore changed the plan of procedure in this way. My fingers had freely detached the divided peritoneum so that the bowel and the entire contents of the sacral curve were liberated behind nearly to the tip of the coccyx and in front to the edge of the prostate. This gave me room to tie around the bowel some three inches from the anus a couple of iodoform tapes about an inch apart. The intestine was then cut through and being free was readily raised out of the abdominal wound and held aside by an assistant. The lower end of the rectum was then seized by forceps in the hands of an assistant who drew it down and out of the anus in an everted condition. Untying the tape that closed this everted bowel, its lumen was opened so that a long pair of forceps could be carried through it up into the pelvis, when the end of the upper bowel was brought down within its clasp and by it the latter was drawn through the lower bowel out into the world. A couple of needles passed through the invaginated ends of the bowels, near their margins, allowed easy union by sutures of their edges with their knots inside the bowel and replacement of the same then was done. After the peritoneum had been sewn together and to the bowel, so that the pelvis and general abdominal cavity had been separated from one another by the peritoneal shelf, I deemed it best to provide drainage from the peri-intestinal space below by a tube introduced from just in front of the coccyx. These details will be better understood on inspection of Figs. 1 to 4 which accompany this paper.

The outcome made a delightfully satisfactory operation and its success justified its repetition in two other recent cases, all of which are here appended. Two of these recovered and one died, not from any peritonitis, but from a persistent diarrhea without temperature elevation. In the two that recovered inspection shows no recur-

[1] Lancet, August 27, 1892.

rence, eighteen months and nine months respectively after the operation. It was necessary in each case some three to six weeks afterward to use a No. 7 or No. 8 Wales rectal bougie, for there was somewhat more stenosis than is seen in the reunion of peritoneally covered bowel-ends. This, however, was to be expected in a measure. The patients are well and in good health, and have one or two movements daily with ease.

Some points are worth touching on a little more fully.

Concerning the Division of the Peritoneum.—

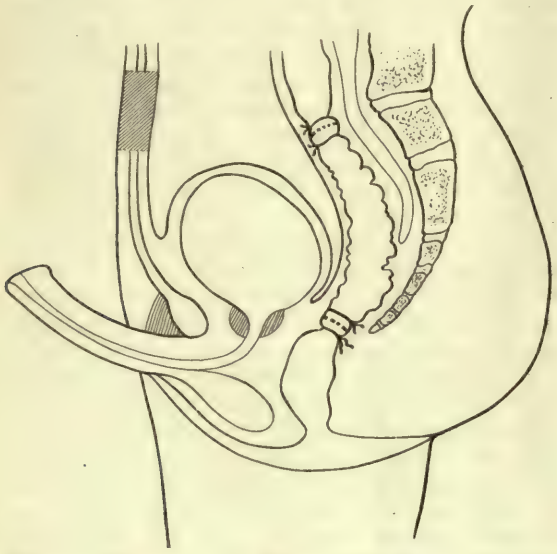

Fig. 1.—Tying off the tumor through an abdominal incision after separating the peritoneum from sacrum and bladder (or vagina).

By drawing the neoplasm backward the folds of the peritoneum stretching from the bladder in the male and from the uterus in the female are rendered prominent and a small cut is made in each; through these openings a pair of scissors curved on the side, or the common bandage scissors, can be introduced just under the peritoneum and this divided up to the bowel across and behind it. A transverse cut across the front of the bowel joining the two knife punctures frees the bowel entirely and by pushing downward anteriorly the prostate is soon reached. However, before peeling off the sacral tissues, I have found it advantageous to search for and to tie the superior hemorrhoidal artery, as this renders the operative field nearly bloodless. This exposure of the lateral curve can be carried much further upward should necessity arise in a hunt for enlarged glands. If the lower blade of the scissors is kept persistently against the under surface of the peritoneum no risk of damage to vessels, nerves, etc., is incurred.

As to Surgical Cleanliness.—The risk of this and similar procedures is, of course, the probable abdominal sepsis from the divided ends of the bowel. I have not only exercised generally particular care, but, as soon as the lower division has been accomplished, have touched the divided exposed mucous membranes with pure carbolic acid which is promptly washed off with alcohol, and similarly treated the upper divided gut as it rests outside the abdomen. Prior to putting in the final sutures and while the bowel-ends protrude from the anus, this cauterized portion was cut off also. After the erosion of the lower bowel the whole pelvis is repeatedly washed out by sterile salt solution, being under good exposure by the retraction of the intestines above by pads, or by a broad wire-handled retractor, three by eight inches, covered with gauze, which admirably keeps them back like a diaphragm. I prefer this to a diaphragm that Maunsell originally proposed.[1]

The Anus and the Drainage.—In my first case to enable me to extract the neoplasm by traction I freely divided the anus backward with somewhat prolonged impairment of power. In the other two cases only stretching in the usual way was resorted to. In all the cases a short drainage-tube was carried up to the site of the line of suture and inside the bowel was placed a small rubber tube covered with iodoform gauze. The signal precision of this operation, its freedom from hemorrhage and its thorough exclusion of the area of trauma from the peritoneal cavity led me to hope that it may come into more general use; it conduces to the desired end in such diseases, which is more thoroughness in their extirpation.

It is especially important to have a reliable assistant in this procedure. He should evert the

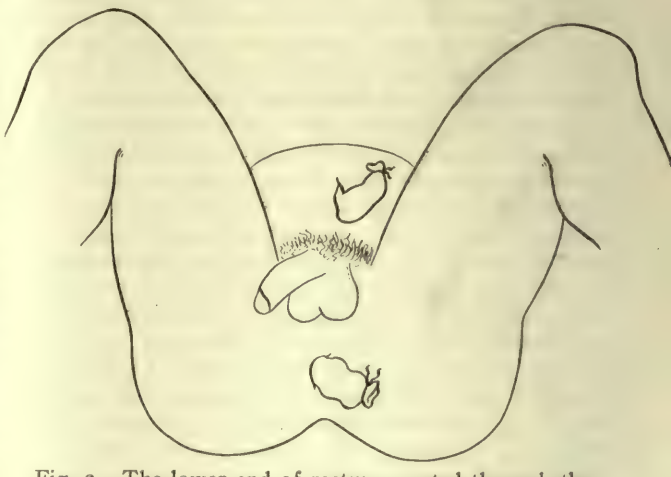

Fig. 2.—The lower end of rectum everted through the anus and the upper bowel drawn out of the abdominal cavity.

lower bowel, pull down the upper, conduct the suturing, replacement and drainage. The surgeon in charge had better restrict himself to the interior abdominal work and thus be able to maintain the required asepsis. It is true that the use of rubber gloves, so easily disinfected, or so readily changed as they are, will often do away with this need.

[1] Loc. cit

Case I.—Mr. C. H., aged sixty-four; referred to me by Dr. Knickerbocker in January, 1900, with the history of pain in the lower bowel for over a year, with constipation increasing in character and with occasional attacks of obstruction. Loss of flesh moderate, not more than ten pounds. Some loss of strength. No anemia. On examination a carcinomatous mass could be felt about four inches from the anus. Into this the tip of

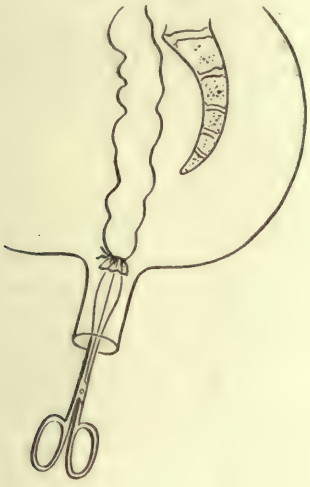

Fig. 3.—Upper bowel drawn out through everted lower end of rectum.

the forefinger could be passed sufficiently to enable one to determine that the mass above could be moved quite freely. The upper end of the neoplasm could not be reached.

On January 30, 1900, rectal extirpation by Maunsell's method by abdominal section was attempted, with the assistance of Drs. Frank Hartley, Foote and Taylor. Nitrous oxide gas with

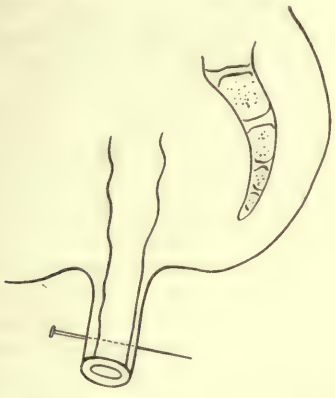

Fig. 4.—The ends of the two portions of the bowel sewn together.

oxygen was administered by Dr. Goldan. The bowels had been freely moved on the previous day, as I do not like fecal flooding at the time of operation. After the abdomen was opened a transverse septum of gauze, three by eight inches, stretched on stout copper wire was used to retain the the small intestines above the pelvis. It answered its purpose very well. The peritoneum was cut through on each side of the rectum back to the sacrum, also across just behind the bladder. The contents of the sacral curve were peeled off after tying the middle sacral artery. Several small glands were found here. None could be found above the upper limit of the peritoneal division. An attempt was made to pull down the growth by means of a loop of tape drawn through the upper part of the tumor out through the anus, but this failed although the anus had been enlarged and the rectum itself previously dilated by Dr. Hartley with specula and fingers. The tugging not only failed, but tore the gut badly and was abandoned as impracticable. Therefore a tape of iodoform gauze was applied around the rectum below the tumor and a clamp was fastened just above this. On dividing the intervening intestine it was possible to lift the tumor out of the abdominal cavity, and, after a little further liberation of the peritoneum covering the mesentery, the tumor, which

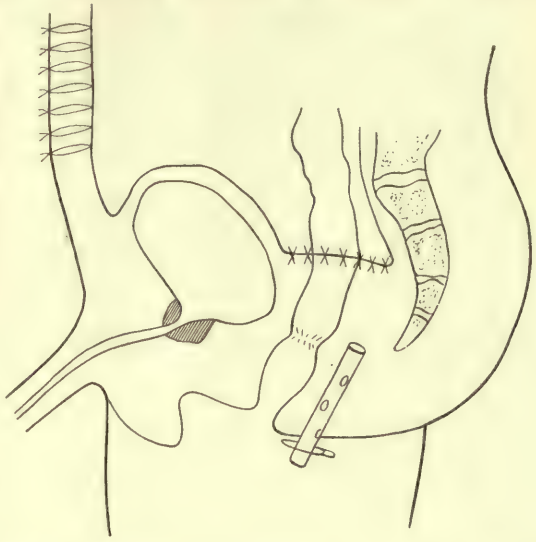

Fig. 5.—The everted bowel replaced, with posterior drainage and the divided peritoneum so sewn together as to shut off the general peritoneal cavity from the pelvis.

was four inches long, its upper limit being between eight and nine inches from the anus, was cut off. The tied end of the bowel remaining was sterilized with pure carbolic acid as was also the anal end of the rectum left in the pelvis. Dr. Hartley with forceps then seized the lower portion of the bowel and, everting it, caused it to protrude through the anus. Another introduction of the forceps through the everted gut caught the end of the upper bowel and this in turn was drawn through the everted anal portion. Both ends of the rectum were held *in situ* for a time by two long straight needles passed across their wall at right angles near the suture line, which was freshened by cutting off the cauterized flaps. Between 20 and 30 interrupted fine chromicized catgut sutures were used to close the circumference of the bowel. I then drew up into position by slight traction the

united portion. The divided peritoneal edges were carefully sewn together by interrupted sutures after free irrigation of the raw pelvis, which was drained from below by a drain inserted through the wound and reaching to the coccyx. The operation lasted over three hours by reason of the time spent in endeavoring to pull down and drag out the tumor in accordance with Maunsell's directions. The patient did not suffer from shock, but there was complete muscular and sensory paralysis of his entire left arm. During the anesthesia both arms had been fastened above his head which latter was done for ease of working the somewhat cumbrous apparatus of the mixed anesthesia, and had been kept strongly to the right side thus all the more stretching the brachial plexuses. It may be said that it required some six months for him to recover from this, my first, experience in positive paralysis. His recovery from the operation was satisfactory and prompt. He was up and about in three weeks. A slight mural abscess delayed a little his progress. He noticed at the end of six weeks some little trouble in defecation and I found on examination that a cicatricial contraction linear in character, had occurred which yielded to a No. 3 to No. 8 Wales bougie in the course of a month. Since then he has been in good local and general condition.

Case II.—Mrs. A. H. T. Admitted to Roosevelt Hospital, October 17, 1900, with the following history. Six months before admission she noticed that her stools were preceded by the passage of blood and mucus. This continued without any considerable increase. Six weeks before admission pain was felt deep in the pelvis; it was not increased by defecation, was aching in character, but worse at times. No diminution in size of fecal mass. Bowels regular. Slight loss of flesh. Her general condition was good. Examination showed three and one-half inches from anus an ulcerated mass one and one-half inches in width attached to anterior and left side in a sessile manner; the finger could not reach above it; it was slightly tender, but not markedly hard; there was no constriction; no glands were felt; no bleeding from examination; rectum slightly movable.

October 27, 1900. Anesthetic, gas and ether. Trendelenburg position. Celiotomy in median line; intestines retracted upward by gauze-covered retractor. Tumor found running upward and involving the upper part of rectum and lower part of sigmoid. Peritoneum divided on each side of diseased gut. Four and one-half inches excised between ligatures. Distal stump invaginated through rectum and anus. Ligature removed; proximal stump then drawn through invaginated distal portion; a circular enterorrhaphy done outside rectum. Gut again retracted into abdominal cavity; peritoneum sutured over it. Abdominal wall closed. Drainage tube inserted posterior to anus. Operation almost bloodless. Carcinoma involving lower sigmoid and upper rectum along anterior and lateral walls for three inches; glands in hollow of sacrum not much involved; tumor movable. Uneventful recovery; bowels moved on the ninth day; all drains removed and wounds healed by the fourteenth day; slight discharge of muco-pus from rectum for two weeks more. The patient then developed pulmonary tuberculosis; transferred to medical side from which he was discharged improved, December 20th, 1900. Three months after the operation a smooth hard stricture was felt, admitting No. 6 and No. 7 Wales bougie. Movements twice a day. In good general health when seen in May, 1901.

Case III.—Man aged fifty-four years, sent to me by Dr. Forman of Freehold, N. J., with a history of rectal trouble of many months' duration. On examination a carcinomatous ulceration was found stretching from about two and one-half inches from the anus upward, so that deep above the pubis its impulse from below could be felt. The patient was only in fair condition.

The operation was done in the manner previously described, but it varied in two ways. There was much more than the usual oozing, and, after opening the peritoneum and separating the wall, it was found that the infiltration of the carcinoma extended along the right lateral wall toward the anus, so that there was at this point not more than one to one and one-half inches of sound intestinal wall. This in its eversion demanded its truncation and also additional loosening of the upper bowel from its mesentery. The other steps were as usual. The patient did well for twenty-four hours and then began to have a diarrhea, without pain, vomiting nor distention, which was uncontrollable and which brought about a fatal issue at the end of the fourth or fifth day.

A CASE OF EMBOLISM OF ONE OF THE RIGHT LENTICULO-OPTIC ARTERIES COMPLICATING PNEUMONIA, WITH AUTOPSY.

BY CHARLES J. ALDRICH, M.D.,

OF CLEVELAND;

LECTURER ON CLINICAL NEUROLOGY AND ANATOMY OF THE NERVOUS SYSTEM IN THE CLEVELAND COLLEGE OF PHYSICIANS AND SURGEONS; VISITING PHYSICIAN AND NEUROLOGIST TO THE CLEVELAND GENERAL HOSPITAL AND DISPENSARY; NEUROLOGIST TO THE CLEVELAND CITY HOSPITAL.

H. W., aged eleven years, male, white, born in United States, was seen in consultation with Dr. A. S. Elliott, May 16, 1900. The patient had previously had good health and his father and mother are both healthy people. Three children of this family have died; one from an aural abscess; one from pneumonia and the third, while in apparent good health, was seized with convulsions and died without regaining consciousness. There remain three other healthy children. The mother has never had a miscarriage nor stillbirth.

The boy's illness began May 3rd. He returned from school complaining that another boy had struck him on the left shoulder with a baseball bat. His brother, with whom he slept, said that he tossed about all of that night. A physician was called in the morning who thought the dif-

ficulty was due to a cold and left some medicine, but called later in the day and found the boy in delirium. He had quite a high fever and a dry hacking cough. The next morning when the physician called he found the patient better and said that it was unnecessary for him to call again.

The boy became delirious before night and Dr. Elliott, the family physician was summoned in the morning and found him with a temperature of 104° F.; rapid pulse; coughing; spleen slightly enlarged and abdomen tympanitic; slight diarrhea and stools of a pea-soup green. He made a diagnosis of croupous pneumonia with a possible typhoidal infection. The high temperature continued for several days and then began to recede gradually, although he continued in delirium.

Four days preceding my visit, and on the ninth day of his illness, he began to have general jerky, choreic movements which continued without intermission for over twenty-four hours, at the end of which time, it was noticed that he no longer moved the left arm or leg; the face, however, was not drawn to one side. The pupils were wide throughout his illness. There had been no skin eruption and he did not complain of stiff neck, neither was there any rigidity of the neck or spine. Since the advent of the paralysis he had lain in bed with his head turned toward the right with a conjugate deviation of his eyes toward the same side—away from the paralyzed side.

Examination.—The boy is of good height for his age, rather thin, face is pale. He lies with his lips apart, between which can be seen his teeth covered with sordes and a foully-coated tongue. It is observed that he does not move the left arm or leg, that his head is turned to the right, and, also, that both eyes are looking toward the same side, a typical conjugate deviation—turning and looking away from the paralyzed side and toward the brain lesion, as it were, thus demonstrating the lesion to be destructive in character. The pupils are widely dilated and react slightly and slowly to light. There is no evidence of other disturbance of the ocular muscles. Neither are the facial muscles weak nor paralyzed.

The ophthalmoscope fails to reveal any changes in the disks. He answers questions in a whining tone and in monosyllables only. He takes quite a good deal of nourishment and seems to digest it. He swallows well, sleeps well, and during our examination had an involuntary movement of the bowels. The abdomen is flat, liver slightly enlarged and the spleen not palpable. There is neither rigidity of the back nor legs, and, except the muscular spasm which turns his head to the right, there is no rigidity of the neck. *Tâche cérébrale* is very marked, knee-jerk cannot be elicited on the right side and is so faint as to be questionable upon the left. The various skin reflexes on both sides of the body are normal and there does not seem to be any loss of sensation. Titulation of the sole of the right foot produces the normal movement of the toes, but Babinski's sign is present in the left foot. The pulse is 115 and slightly irregular. The pulmonary second sound is practically absent and the normal pauses between the sounds are so greatly shortened as to have a fetal character (embryocardia). There is a slight increase of dulness to the right of the sternum and we are of the opinion that his right heart is greatly engorged and that dilatation and rapid failure are taking place. The respiration is hurried, but regular. Coarse râles can be heard over the left lung, but the right lung is quite dull on percussion. Over the latter lung, about its center and upper portion, can be heard bubbling râles, evidence of beginning resolution. Temperature in the rectum 103.5° F.

Diagnosis.—It was comparatively easy to make a diagnosis of a destructive lesion which involved the leg and arm fibers of the internal capsule posterior to the facial fibers, without, however, producing marked changes in the sensory tract and the extreme hinder part of the posterior limb of the capsule. Since we were unable to test adequately for hemianopsia, it was impossible to be positive about the extent of the injury backward, but we did not believe it to extend far back, since, as it was stated before, there were no marked changes in the integumental sensorium.

Our ability to determine the nature of the lesion, however, was not so exact. Hemorrhages into the brain substance occur more frequently in the young than in the middle-aged, but are far more frequent in old age than any other period of life; it is also true that cerebral hemorrhage occurs not uncommonly in acute infectious disease characterized by high temperatures since the effect of the high temperature and the toxins occasioning the same seems to produce a fatty degeneration of the arterial coats, which, with the high blood-tension, are liable to rupture. Pneumonia being a disease characterized by a low blood-tension, one would hardly expect a hemorrhage from rupture of the arterial wall, and especially does this obtain in this case, since the heart was evidently in a state of acute dilatation and was rapidly failing. The tendency of the blood in pneumonia to develop a very large amount of fibrin, the presence of a failing right heart—so liable of itself to cause clotting—made it quite natural that we should think of a bit of fibrin being driven into one of the cerebral arteries, hence a diagnosis was made of cerebral embolism of one of the smaller cerebral arteries and quite certainly one of the lenticulo-optic arteries. An unfavorable prognosis was given.

The patient died on the following day from heart exhaustion following the acute dilatation. A postmortem examination was made, Drs. Elliott and F. Y. Allan assisting. The liver was found slightly enlarged; spleen practically normal in size. There was evidence of considerable irritation of the mucosa of the intestines; this irritation was undoubtedly the cause of the

tendency to diarrhea which was manifested during the whole course of the boy's sickness. No evidences of typhoidal ulceration were discovered. The right lung was almost completely consolidated, resolution was advancing, however, in such a manner as to indicate that, had not the brain been subjected to embolic insult, recovery would have been quite certain. The left lung was slightly engorged, but contained no pneumonic deposit; there were no pleural adhesions, and but a small quantity of fluid was found in the right pleura. The heart sac contained a slight excess of fluid, and the right heart was sensibly flabby, dilated and thin. Its cavities contained some very firm fibrinous clots which were probably formed during the death agony, if not some time before. They were certainly much more firm than usually found in the hearts of those dying from pneumonia.

After removal of the calvarium the brain and its membranes seemed normal, with the exception that the vessels were slightly injected. On section of the brain an area of softening was found occupying the region of the posterior half of the right lenticular nucleus, and the hinder part of the posterior limb of the internal capsule, involving to a slight extent the optic thalamus. A later search revealed a complete embolism of one of the middle lenticulo-optic arteries. The vessels in other portions of the brain seemed to be perfectly normal and we were unable to find other patches of softening. Without result the spleen and liver were also carefully sectioned in our attempt to determine the question of further embolism.

In examining the literature of cerebral embolism complicating pneumonia, one is struck by its very rare occurrence. This seems peculiar when we take into consideration the great tendency on the part of the blood in pneumonia to develop fibrin.

Da Costa has reported six cases of phlegmasia alba dolens in pneumonia. Anders states that venous thrombosis is seldom seen and embolism of the larger arteries is a rare complication. Also, that cerebral embolism causing aphasia and even hemiplegia has rarely been observed.

Loomis in speaking of the cerebral complications of croupous pneumonia says: "A very rare occurrence is partial paralysis of the muscles which were involved during the convulsive period; such paralysis is often permanent."

Osler says: "A rare complication is embolism of one of the larger arteries. I saw an instance in Montreal of embolism of the femoral artery at the height of pneumonia, which necessitated amputation at the thigh. The patient recovered. Transient aphasia has been met with in a few instances, setting in abruptly with or without hemiplegia."

I have been unable to find other references to the subject in any recent literature, but it is possible that such cases are not as rare as we would infer from this partial examination of the subject.

612 Prospect Street.

AN ATTEMPTED INVESTIGATION OF SOME CHRISTIAN SCIENCE "CURES."

BY LAWRENCE IRWELL, M.A., B.C.L.,
OF BUFFALO, N. Y.

ALTHOUGH epidemics of mental disease which have usually been connected with either religion or finance have been quite numerous in the past, the prevalence of them whether in this country or elsewhere should cause no surprise when we remember that man is a gregarious animal, that the average individual is always ready to believe some part of whatever is suggested to him, and that the world has never been destitute of lunatics and charlatans whose object has been—and is—to pose as leaders and philanthropists. If the external manifestations of the contagious mental disorders of to-day differ from the various forms which history has recorded, the explanation may be easily found in the ever-present evolution of man and of his environment.

"The vast majority of persons of our race," says Francis Galton in his Inquiries into Human Faculty, "have a natural tendency to shrink from the responsibility of standing and acting alone; they exalt the *vox populi*, even when they know it to be the utterance of a mob of nobodies, into the *vox Dei*, and they are willing slaves to tradition, authority and custom. The intellectual deficiencies corresponding to these moral flaws are shown by the rareness of free and original thought, as compared with the frequency and readiness with which men accept the opinions of those in authority as binding on their judgment."

Last September it occurred to me that it might be desirable to investigate some of the remarkable "cures" made by Christian Scientists, of which we have heard so much. Having read a letter in the *Buffalo Express* concerning a "cure" of consumption by Christian Science methods, I wrote to the author of the communication asking if by "consumption" he meant phthisis, and if he would favor me with the name and address of the person who had been "healed." My efforts were in vain. My letter directed to Willard S. Mattox, New York City, was returned to me by the post office. The gentleman could not be found. His address is not in the directory for 1900. The reader can place his own estimate upon the value of the testimony of a man whose residence is so difficult to discover that mail does not reach him.

I was recently given a copy of the *Christian Science Sentinel* of January 31, 1901. This contains three testimonials. One of them is from a lady who asserts that Christian Science enabled her daughter, aged fifteen years, to have her teeth attended to without the dentist causing the child any pain. The mother, whose address is Jacksonville, Fla., has not answered my letter asking for the name of the dentist, so that I have been unable to get any details concerning this remarkable "demonstration."

A little more than a column is taken up with the testimonial of a woman who claims to have been cured of a "cancerous growth" on her breast

and under her arm by studying Science and Health with Key to the Scriptures. The story reads very well, but I am in a position to prove (1) that the carcinoma was removed in a hospital by an eminent surgeon about seven years before the woman became a Christian Scientist, and (2) that the superintendent of the hospital has in his possession a letter from his patient, written two years after the operation, in which no mention is made of any return of the carcinoma.

I refrain from wasting valuable space by giving further details.

The third testimonial is from a woman who asserts (1) that she has been relieved "of a growth," and (2) that her husband has been "healed" of smoking and the liquor habit and of Bright's disease, pronounced by the physicians to be in its worst form?

First, as to the husband, the physician to whom I wrote has informed me that neither he nor his colleague ever found proof that the patient was suffering from nephritis. His condition was due "to congestion superinduced by excessive use of alcoholic liquors." The Christian Scientists, of course, deserve credit for the man's reformation, "which," writes the doctor, "is all the cure that has been effected." The man, having ceased to drink heavily, and having stopped the excessive use of tobacco, has given his kidneys and liver an opportunity of resuming their normal functions. As he never had "Bright's disease," the "healer" cannot be said to have cured that disorder.

Concerning this man's wife and the "growth" of which she was relieved, she gives me to understand that she made the diagnosis herself, and from her very long letter it is quite evident that this "growth" only existed in her imagination. I am told that fermentation in the stomach or intestines frequently produces the feeling of a lump. Mrs. M. does not pretend that any physician ever told her that there was a growth in her stomach. I cannot ask for the publication of this woman's letter, as it would occupy almost a page. "Tumer," "dun," "Piticular troubel," "simtons," "pureafying," "softning," "my husband never wrights," and "very Trouley yours," are samples of what it contains.

On March 20th I visited a "healer," Mrs. L., having previously been informed that she was an educated person who had taken a course in medicine. I soon discovered that this was an error and that she was quite ignorant of the difference between apoplexy and epilepsy. She professed to have cured the former, which is, of course, a symptom rather than a disease. It must be remembered that I am not a physician, but her description of the case suggested to my mind an ordinary epileptic fit, such as I have often seen on the street. The sufferer recovers in a short time without medical aid, and, in due course, repeats the performance. When I asked the lady if she did not mean epilepsy, not apoplexy, she answered that the "patient" never had another fit, but that she had not studied "physics!" In reply to my enquiry "How did you make your diagnosis?" Mrs. L. said, "I cannot explain; we do not use the word diagnosis." The thought came to me that it must be "apoplexy." Answering a further query, she informed me that she had never before witnessed a case of apoplectic seizure.

I am well aware, I need hardly say, that no scientific man ever wastes his time in arguing with a person who suffers from delusions. But, as this was my first (and probably my last) interview with this woman, it seemed desirable that I should attempt to ascertain whether the fallacies with which her mind was burdened could be removed by argument or not. When, therefore, she made the interesting assertion that the heredity of consumption was due to one generation after another believing that the disease was transmitted, I flatly contradicted her and explained in non-technical language the history of the Koch bacillus, the evidence of the heredity of the phthisical diathesis, and the impossibility of a micro-organic disease being hereditary in the proper sense of the term. I made no impression whatever, for her last word upon the subject was, "The doctors always call consumption a hereditary disease." This expression was not sufficient to convince me that the woman was the victim of delusions, nor was I convinced when she told me that, having read some of Darwin's works, she was sure he was wrong in his belief that "life came from dead matter." She was unable to remember the name of any single book written by the great biologist.

Replying to my question "Do you assert that there is no such thing as disease?" the lady talked for about fifteen minutes upon the Old Testament and the New without giving me any "information," except that the Old Testament was originally written in Greek! Upon my interrupting her dissertation, which had nothing to do with my query, she assured me that she could not answer unless I permitted her to begin at the beginning. As my time has some value, I dropped the subject and asked, "Can one become a 'healer' in twelve days by attending the Boston Christian Science School?" I understood the answer to be in the affirmative, provided the student does not want to "treat obstetrical cases," but further conversation led me to believe that my informant meant gynecological cases. I then asked the following questions:

"Mrs. L., will Christian Science eventually be able to do away with death?"

"That will be the last thing for us to overcome."

"When a healer is called to treat a sick person, is the first order 'dismiss your physician?'"

"Yes; when the patient recovers, the doctor would claim the credit. Besides, his methods interfere with our spiritual cure."

I am afraid that I have been unable to remember the exact words of the answer to the last question.

Up to this point, with the exception named, I had ignored every absurdity uttered by this woman, and had asked a further question as soon as she ceased answering the previous one. As I was about to leave, she volunteered the statement that prior to becoming a "scientist" she had been unsuccessfully operated upon by a surgeon twenty-nine times in the course of two years, chloroform having been given to her upon each occasion! This seemed to be strong evidence of delusion. I now changed my method, with the object of trying to find out whether Mrs. L. was to be regarded as a lunatic or as a charlatan. I am bound to confess, however, that delusions alone do not, in my opinion, prove insanity. We have no absolute test of insanity, because there is no distinct and dividing line where sanity ends and insanity begins.

Having defined the word "operation," I told Mrs. L. that 29 operations in two years meant an average of more than one operation per month. She gave me the name of the "operator," after a good deal of pressure, and said that he not only operated, but also administered the anesthetic! No other person was ever present, she said, except "a lady" (nurse, I suppose), whose name she refused to divulge. Having had a legal education, I am not of a credulous turn of mind and I never believed one word of this statement. Nevertheless, I have investigated it very carefully.

This "healer" tells the story of twenty-nine unsuccessful operations to her "patients," and then informs them that she was eventually cured of stricture of the rectum by Christian Science. The tale is devoid of foundation. No surgeon habitually performs operations which need the use of an anesthetic without the presence of a second medical man. No surgeon operates once a month for two years. Moreover, the late Dr. Q., whose name I *dragged* from this woman, was a very skilful and much respected physician, not a surgeon, who never made a practice of operating at all. His son informs me that the whole story is untrue, as far as operations are concerned. The late Dr. Q. may have *treated* Mrs. L. for stricture of the rectum by gradual dilatation—or otherwise.

As I have already explained, I am not a physician, much less an alienist; outside a limited amount of legal experience, I have had little opportunity of studying mental pathology, but it is fair to say that I have read, with the greatest care, the works of Clouston, Maudsley, Spitzka, Griesinger, Mercier, Hammond and others. In my opinion, formed in the course of one interview of an hour's duration, Mrs. L. believes all she relates and is not an impostor. I must add that further conversation with her and investigation of her antecedents might alter my opinion.

At one of the hearings at Albany upon the Bell Bill regulating the science of treating disease by uneducated persons, a speech was made by a Buffalo "healer" named George H. Kinter. I was not present, and consequently do not know of my own knowledge what he told the Committee, but according to the *Buffalo Express* of February 14th last, on the subject of diagnosis, Mr. Kinter said he had been a reader for twelve years and had not yet been accused of killing anyone or making a mistaken diagnosis."

Within the past three years this same Kinter has been charged with manslaughter in neglecting to summon medical aid to a child who was suffering from pneumonia. The child was not Kinter's; its parents, poor dupes, were Christian Scientists, and he was attempting to "heal" it by his absurd methods. It is true that the Grand Jury did not indict him, but that does not affect the point under discussion. If he should see this article, he will, of course, deny the accuracy of the report in the *Express*.

The *Christian Science Journal* for January last contains fourteen testimonials from persons who profess to have been "healed," and who give their names and addresses. A suitable letter was sent to thirteen of these, requesting details, and a stamped envelope was inclosed for an answer in every instance. Two persons have not replied, and two of my communications have been returned by the post office. Of the remaining nine "scientists" who have answered, only four can be said to write fairly accurate English. Three of the others are utterly illiterate. In order to demonstrate to some extent the accuracy of this assertion, I give here the testimonial given in the *Christian Science Journal* by Mrs. McC——, of M——, and her letter to me. The former was, no doubt, written by a "healer," and afterward signed by the dupe.

Testimonial from Mrs. E. McC. in Christian Science Journal.

"When only six years of age I was taken with epilepsy. We sought first one doctor, then another, for help, but there was none. I suffered not only from the fits, but other diseases took hold of me. For weeks at a time I would be perfectly helpless with rheumatism. Add to all this two operations which brought no relief, and does any one wonder that for me life seemed a mockery? One day about four years ago my husband stopped at neighbor's and found them rejoicing over the recovery of their daughter, who had been deaf for fourteen years, and now had received her hearing through Christian Science. Upon learning what had healed her my husband hastened home with the good news that he had at last found something that would heal me. Full of hope that it would be even as he said, we went to the healer who had brought back the girl's hearing. In two weeks' time I was healed and I am well and strong, able to do any amount of work, to the amazement of my friends who knew of my condition. I am now a member of the Mother Church, and my heart overflows with gratitude to Mrs. Eddy, who has taught us how to know God and be free. I am also grateful to my healer who was instrumental in bringing me health."

Letter from Mrs. E. McC. to L. Irwell, Feb. 8, 1901.

"Dear Frend I Reseaved your Kind and wilcom leter which gave me Plesher to hear that thare is more lucking for this Blesed truth I Had the Clame for 22 years Ever Since I was 6 years Ould Thare is Noting in posiable for God be fore I Came to C. S. I lucked like a Shadow on the wal Now I way 175 Pounds and I can Due all kinds ove work and I go to C. S. meatings no mater How the weder may be we most take ony C. S. with a Good oniest Hart I Remane your Sister in truth

"Mrs. E.——— McC.———,
"M..... W———

"Hoping to Hear from [you] soon"

I have frequently been told of the high order of intelligence of the supporters of Eddyism, but my experience leads me to the conclusion that most Christian Scientists are extremely ignorant people. What else is to be expected when the woman Eddy herself writes of "the emptiness of knowledge, the nothingness of matter and its imaginary laws. . . "? (This quotation is taken from J. M. Buckley's "Faith-Healing," page 246.)

Testimonial No. 14 appeared to me unworthy of serious investigation. It is signed by a woman, Mrs. Annie S———, wife of the master (*i.e.*, the Head) of one of the colleges of the English University of Cambridge, who relates that her husband, a disbeliever in Eddyism, was assisted in getting rid of a cough by his spouse's "scientific" methods, and did not find it necessary to use some lozenges which he had bought.

Mrs. J. K. of E—— relates how she was healed of catarrh in the head and "had a tumor disappear also." Unfortunately, she was unwilling to tell how she knew that she had catarrh, although I requested her to do so in three different letters. She assumed that I was suffering from some disorder similar to her's, and advised me to visit a Buffalo "healer," whose *"adress"* she gave. Having implored me to be *"obident,"* she concluded with, "Read Mark 5-25 & 26 also John, 4-12 I am yours sincerely in Truth and Love." It seems a pity that I have been unable to induce this woman to favor me with the name of the physician who treated her for catarrh.

Mr. A. L. F. of S—— got a hot cinder into his eye. He testifies to the cure of this serious affliction by the day following the accident. But his own witness, who is not a "scientist," writes me that the eye "was all well in a couple of days." Mr. F's words in the *Christian Science Journal* are, "By the next morning all trace of the eye having been burned at all had disappeared." Even if his statements were correct, nothing remarkable has occurred. He evidently forgot to "coach" his witness, from whom I have now received a second letter, which reads as follows: "I read 'Science & Health' during the period Mr. Fink hurt his eye—the book may seem reasonable to some persons, but to me it does not—especially in this enlightened age—as I told you before, I have not the least faith in the work, and further I do not care to discuss the subject—and I wish to say that I do not want my name used as a testimonial in Mr. Fink's incident. Strong will power, in my mind, has a great deal more to do with a case like Mr. Fink's than anything else—I have seen *too* many cases result fatal in this city to have anything to do with Christian Science."

Mr. G. E. C. of C—— appears to have had some curious experiences. He has "had two cases of broken toes and two of broken fingers and thumb healed without even a bandage, court plaster, or bathing of wounds, one a very bad compound fracture." He did his "own work on these cases. The battle was the Lord's—He delivered him." Nor is this all. In a street-car collision he was thrown "fifteen feet" . . . but "escaped with only a small bruise on one finger." . . "The claim of shock seemed to come up afterward, and was met and mastered by a sister scientist here. I could write all day of His loving kindness, and of His mercy which endureth forever."

Mr. C.'s reply to my first letter was dated at C——, but with neither street nor number. He informed me that his "use of the word compound was different from the doctors," and that his "thumb was broken at first joint—set type with it every day until it was completely healed, also did some work with other finger, working eight hours a day in both cases." His final sentence is "Are you a Christian Scientist?"

As I considered this curious epistle most unsatisfactorily, I again wrote requesting the gentleman to kindly tell me how he knew that his thumb was broken at the first joint, and in what sense he used the word "compound." I ended my letter by saying "I have no interest in this matter beyond a desire to ascertain the truth."

Within a few days my communication was returned to me with the last sentence underlined, and the following words written upon the back of it, a postscript upon a separate piece of paper being enclosed. This masterpiece is worth printing.

"There is but one TRUTH. You can find it in *Science and Health* and the Bible—by reading the two combined—as to how I *knew* my thumb was broken—I knew it the same as you would know some portion of your body was injured—that's the best way I can explain it to you. I also by the same evidence know when it was healed—my address is No. 9 West 4th St.—am engaged in newspaper work—have no time for answering letters for mere gratification of *curiosity* but am willing to help a brother in need of help—the work I am in really takes up too much of my time—which I should prefer to devote to other things. In haste, etc.

"P. S.—As to the question of knowing—there are a large number of people who *know* some few things besides the men of letters—even little children are sometimes smarter than their parents—and an animal *knows* when he's hurt."

Mr. J. A. K. relates that he fell "a distance of about forty feet on a pile of broken rock . . . but broken bones were skilfully set" by a surgeon. For eight years he "continued under the care of different doctors of *materia medica,* and tried almost every so-called remedy suggested for rheumatism in one of its worst forms, sometimes having relief for a few days." He admits having been a "tippler," and relates that within a month of beginning to read *Science & Health* he was healed of rheumatism and "tippling."

On March 1st, I wrote to Mr. K., asking him to kindly favor me with the names and addresses of some of the physicians who had treated him. To this request, he sent me the following answer, which reached me on March 14th.

"Your letter of Inquiry at hand as to my sending you the names of the different Doctors who treated me for Rheumatism, I cannot do so without their consent although There are one or Two of them Residing in Scranton. I have not as yet been able to see them, but will at the earliest possible time. and then if they are willing will do as you wish. One of these *Phisicians* is also the one who attended me at the time of the *acident* I can furnish you the names of some of my acquaintances. who are well acquainted with the facts as stated in my testimonial. I have had so many proofs of the Potency of Truth in overcoming error of different sorts in my family for more than four years. That I do not hesitate in offering what little I have to any honest Inquirer. I know that the Teaching of Our Text Book S. & H. with Key to the Scriptures By Mary Baker Eddy are True The Truth that makes free. Will *comunicate* with you again at my earliest convenience and furnish you what you desire if *permited.*"

Having heard nothing further, on March 26th I again wrote to Mr. K. reminding him that my request for the names of his former medical attendants had not been complied with. Upon April 14th, I received a short note from him in which he gives, not the names of the physicians under whose care he had been before becoming a "scientist," but the names of some persons who are said to have known of his "healing!" I never asked him for these names, which are worthless for my purpose, and all I ever requested him to do was to send me the names of his former physicians. I have no hesitation in saying that this man's letters show that his intelligence is limited. (Since the completion of this paper, a further letter, characteristic of Mr. K., has reached me.)

Mrs. A. L. J. claims to have suffered from "stricture of the intestines in two places." She relates that she "was sentenced to the uncertainty of an operation or to sure death without it, by different specalists in Kansas City and by one of the best physicians of this place" (Joplin, Mo.). It is impossible to rely upon Mrs. J.'s statements, since Dr. W. has sent me a full account of her case, and has shown very clearly that he cured her of stricture of the rectum before she became an Eddyite. The treatment lasted from March 12th to June 12, 1900. It is true that Dr. W. did tell her that if treatment failed, an operation might be necessary. Mrs. J. is not an educated woman, and her letter to me, which covers eight pages, written on both sides, is largely devoted to explaining the methods by which I could become a Christian Scientist, instead of giving details of her "cure." Her epistle ends with "I am not looking for patients as I am not a *practioner.*" No useful purpose could be served by giving further particulars.

Mr. C. G. M. "suffered for twenty years with eczema in its worst form." He "tried everything in the line of patent medicines, besides consulting the best physicians," but was told that he would "never be healed." He was "healed" by Christian Science in six months. His wife was "healed" of rheumatism, and his little daughter of inflammation of the lungs in a few hours!" Mr. M. is a professional "healer." His answer is in the handwriting of a woman, and the expressions used are those of a woman. The signature is in the same writing as the body of the letter. Among many curiosities, I notice the following: "If I thought you doubted the truthfulness of my statements I would not answer them. But I think you must be to (*sic*) much of a gentleman for that." Being anxious to investigate these "cures," I sent a second letter repeating my questions. This letter was registered. It appears that Mr. M. has filed at his post office a form of authority for another "healer" to receive his mail. The answer to my second communication gives me no additional knowledge, as the writer refuses to disclose the names of his former doctors, for the bizarre reason that it "might be unpleasant to them," and he ends with an intimation that he must cease corresponding with me. There are some suspicious circumstances connected with this case, in addition to the facts that the man did not sign for his own registered mail, and that his letters are apparently written and signed by a woman. My three specific questions, repeated twice, are ignored.

M. S. R. of F. W. is a child "not nine years old yet," whose testimonial in the *Christian Science Journal* is remarkably well expressed. She says that she had "a belief of scarlet fever," and that her mamma treated her "with Christian Science." She was in bed "only two days," and she felt very much better after her mother had read *Science & Health* to her. The child's testimonial contains the following words: "I have treated papa several times and healed him." Being naturally curious to see a specimen of this prodigy's handwriting, I wrote asking her how long she was home from school with scarlet fever, and of what disorders she had healed her father. After much delay, I received a letter from the child's mother, who tells me that she is the first reader at a Christian Scientist Church, and that "it is 7½ years since the children have had a drop of medicine." It is quite evident that this lady regards me as a lunatic, for she writes that her

infant "began treating when she a little over two years old!" No sane person would believe for one moment that any child of two and one-half years could understand that the word "treat"—even by Christian Science—means. Mr. R. has, it seems, "been healed of many little beliefs by Mary, headaches, sore throats, etc." As these trivial complaints disappear without treatment when the sufferer is an ordinary person, it is very easy to understand in what sense this remarkable infant "healed" her father. The mother says, "We called an M.D. in at the time of the scarlet fever. . . . We were at home for fourteen days, tho' Mary was really only confined to bed from Sunday afternoon till Tuesday lunch." I need hardly say that it has been a great source of satisfaction to me to learn that at least one Christian Scientist father had sufficient intelligence to summon a physician when his child was attacked by a "belief" of scarlet fever.

For the purpose of enabling the readers of this article to form their own opinion of Mrs. A. J. R., I give here my second letter to her and her extraordinary second letter—to call it a "reply" would be an unwarrantable use of that word.

Letter from L. Irwell to Mrs. R., Buffalo, N. Y., April 3, 1901.

"Answering your favor of 29th March, may I ask you to kindly explain to me what you mean when you say that your daughter Mary 'began treating when she was a little over two years old? Do you mean that an infant of two years of age can understand what the word 'treatment,' either in the Christian Science sense, or in any other sense, means? Have you any objection to giving me the name of the physician who visited your children when one of them had scarlet fever?

"Thanking you, in anticipation, for your reply, I am, etc."

Letter from Mrs. R. to L. Irwell, April 5, 1901.

"Your letter rece'd. I answered your last letter in good faith, thinking you were either a Christian Scientist, or intended to be one, Jesus took a little child and set it in the midst of them. I thanked God that these things had been hidden from the wise, and prudent and revealed unto *babes,* and now my turn to ask questions comes —why are [you] asking questions of me. Do you desire this Pearl of great price (Christian Science) If you do, I would refer you to Mrs. Anna V. C. Leavitt, who is First Reader in First Church of Christ Scientist of your city. I am not personally acquainted with any of the Scientists in Buffalo. But I can assure you that all strangers are welcome to the Reading Rooms and to all services. Would advise you to go to a Wed. P.M. Testimonial Meeting. God will lead you and guide you. If I understood the motive of your questions I would gladly help you out. I am indeed thankful that I am trying to be a C. S.

"(Mrs.) A. J. R.

"Read the C. S. Journal for April.—J. H. S. R."

The last testimonial is from Miss K. P. of M——. This lady had "a severe claim of neuralgia," and although tempted to use "hot water to alleviate the suffering," refrained from doing so when she remembered that she "needed no help, but His, no water, but the pure invigorating water of Life . . . which cleanses all impurities." This lady's letter to me is merely a copy of her testimonial in different language. As I occasionally suffer from neuralgia, and as it goes away in due course without any treatment whatever, I cannot avoid the conclusion that Miss P.'s "cure" does not demonstrate the efficacy of Christian Science methods, as far as neuralgia is concerned.

Are Christian Scientists insane? I cannot pretend to say whether any class of persons is sane or otherwise, for, in spite of the opinion of alienists of repute, facts which might prove the insanity of one individual would not, in my estimation, prove the insanity of another. If I insisted that man is not an animal and that a whale is a fish, those delusions would certainly prove insanity upon my part; but perfectly sane women —perhaps men also—can be found who cannot be convinced that both assertions are false. The general education of some of these persons may be fairly good, but they are, nevertheless, unable to appreciate technical definitions. Again, I can produce a sane lawyer who insists that phrenology and palmistry are true, notwithstanding every possible effort to prove to him that these absurdities are mere "fakes." Such cases could be cited *ad infinitim.* In a paper upon the "Relation Between Phthisis and Insanity," read before the American Public Health Association in 1896, I said: "I frankly admit that, in my humble opinion, no absurdity of belief nor extravagance in conduct or behavior is alone conclusive evidence of insanity." To that view I still adhere.

It is not practicable to construct a complete and accurate definition of the term "insanity." The late Lord Justice Blackburn, an eminent English lawyer (and judge), when a witness before a committee of the House of Commons, said "I have read every definition which I could meet with and never was satisfied with any of them, and have endeavored to make one satisfactory to myself. I verily believe that it is not in human power to do it." The same opinion is held by Drs. Bucknill and Hack Tuke in their Manual of Psychological Medicine.

Taking the ground that delusions which prove the insanity of one man do not necessarily demonstrate insanity upon the part of another, I venture to assert that the notorious hypothetical question, which generally consists of a speech with a note of interrogation at the end of it, and which is so much in evidence in law courts when will cases and murder cases are on trial, is absolutely valueless—and often ridiculous. Nor is this all. I contend that delusions *alone* do not prove insanity; and that contention is supported by the

opinion of Dr. Clouston—an alienist of quite the first rank. The following excerpt is taken from the article upon "Insanity" in *Chamber's Encyclopedia,* but the same facts may be found in Dr. Clouston's Clinical Lectures on Mental Disease.

"There is no exact line of demarcation between insanity and sanity any more than there is between light and darkness. There is an undefined borderland through which most cases of insanity pass, between technical and legal sanity and insanity. . . . There is or can be no absolute test of insanity—or of sanity, for that matter. Sanity is best proved by normal self-control, and insanity by the loss of it from disease. The presence of one or more insane delusions was at one time the legal test, but it is not a true or scientific one. The "knowledge of right and wrong" was at one time a legal test of responsibility, in other words, of insanity, by the law, but it has long been given up. Half the lunatics know right from wrong in some degree or other."

Dr. Austin Flint made what I believe was his *début* as an alienist in a law court early this year in the Brush will contest. On cross-examination, the following questions and answers were in evidence:

"Do you believe that if a person was run over by a street car and had a limb cut off, and was bleeding to death, that that person could live if he or she refused the attendance of a surgeon?"

"Oh, no."

"Would such belief be an insane delusion?"

"Not if the person could be convinced that it was necessary to have a surgeon."

Had Dr. Flint made himself familiar with any important work upon mental pathology, he would have learned that "delusion" means a steadfast belief in some untrue idea which, as a rule, personally concerns the victim, and of the falsity of which he cannot be persuaded by any amount of evidence, demonstration, the experience of his own senses, or the declaration of others. The word "delusion" is not applicable to a fallacy which can be dispelled by argument. Dr. Flint's so-called "expert testimony" induced Dr. D. A. Gorton to write a long letter to the *New York Times* and to the *Medical Times,* the object of which was to persuade his readers that the "distinction between persons subject to delusions is that the sane person is amenable to reason and can be argued out of his delusions; the insane person is one in whom delusions are fixed, and who cannot be persuaded of their irrational or delusional character." Apparently Dr. Gorton has forgotten that we have such words as "illusion" and "hallucination." The distinction between these terms is well explained in the Century Dictionary under "delusion"; and this word will have lost its value if it is to be used synonymously with any other word. The amateur alienist, even when eminent in some medical specialty outside of psychiatry, always demonstrates the accuracy as the proverb that "a little knowledge is a dangerous thing."

Some Christian Science "healers" are, I feel sure, very sane—and very shrewd—money-makers. Many of their dupes are merely extremely ignorant persons who are easily imposed upon, for, while everybody boasts of the "excellence" of American education, that "excellence," as it is humorously called, only means ability to read and write. Ability to spell is rapidly going out of fashion, and many school teachers still belong to the "I done" and "he seen" variety.

Of the "scientists" with whom I have talked, some are clearly on the borderland of insanity, and none can be properly described as "educated" in the correct sense of the term; but perhaps my definition of this word might not meet with universal approval. However this may be, the following paragraphs telegraphed to the *New York World* by Mrs. Eddy on February 22d, and published in the *Christian Science Sentinel* of February 28th, are well worthy of reproduction.

"The supposition that we can correct insanity by the use of drugs is in itself a species of insanity. A drug cannot of itself go to the brain or affect cerebral conditions in any manner whatever. Drugs cannot remove inflammation, restore disordered functions, nor destroy disease without the aid of mind.

"Neither life nor death, health nor disease, can be produced on a corpse whence mind has departed. This self-evident fact is proof that mind is the cause of all effect made manifest through so-called matter. The general craze is that matter masters mind; the specific insanity is that brain, matter, is insane."

Comment would be out of place.

This same Mrs. Eddy has written a Key to the Scriptures, and almost everybody will gladly admit the value of a genuine "key," especially to the New Testament. Perhaps I may be permitted to say that I have found Huxley's Science and Christian Tradition, aided by my knowledge of Greek, an extremely valuable "key"; but the great naturalist's work would not be understood by any resident in the outskirts of Bedlam. While all Bible students whose intellects are normal would appreciate a "key" written by the possessor of a high-class education, they must necessarily look with disgust upon any such work produced by a tyro. That the woman Eddy is grossly ignorant is proved beyond peradventure by the following excerpt from Christian Science *versus* Pantheism, a pamphlet of which the high priest of the lastest form of quackery is the reputed author: "*Pan* is a Greek prefix, but it might stand, in the term Pantheism, for the mythological deity of that name."

A Pan-American Exhibition is now being held in this city of Buffalo. If Christian Scientists really believe that the word "Pantheism" is in some way connected with the god Pan, they may also suppose that the exhibition in question is a tribute to this same god. If there are "scientists" who take this view, I hope they will not be deterred by it from visiting the exhibition, for one day there would do much toward educating anybody—even an Eddyite.

The medical profession is united in the belief that the Koch bacillus only attacks those who have either inherited or acquired a special susceptibility towards tuberculosis, due, in all probability, to a lowered vitality of the tissues. Similarly, epidemic insanity only attacks those individuals who have inherited or have acquired the insane predisposition; and just as prophylactic measures, such as a highly albuminous diet, may aid the possessor of the phthisical diathesis in resisting the inroads of tubercle bacilli, so may suitable educational methods assist the individual who has inherited or has acquired a tendency towards insanity in maintaining a moderately sound brain. But it must be admitted that the necessary educational measures are generally objectional to the sufferer, and are not forced upon him without serious difficulty. Men and women whose minds are neuropsychopathic are prone to seek the society of others having similar peculiarities, with whom they have a sympathy of feelings and thoughts. Wild flights of imagination and empty idealistic aspirations, such as they themselves indulge in, excite their admiration, while sober reflection and hard work are repugnant to them. The best tonic for those unfortunates who are predisposed to insanity is the investigation of the laws of Nature; and if our boys and girls can be induced to study natural science and to cultivate whatever powers of observation they possess, the mental epidemics of the future will be few, for the disease will not have a fertile soil upon which to propagate. I have little hope, however, that this prophylactic will be utilized to any great extent, because I have good ground for believing that the zoölogy and botany of the average high school are of the pre-Darwinian type, and the mere classification of animals and plants neither appeals to the reasoning powers nor satisfies legitimate curiosity.

Foolish as extravagances of the character of Eddyism unquestionably are, they should be treated with a certain amount of indulgence, for they are often the least harmful direction which the insane diathesis can take. If it were not for them, many persons who are now upon the borderland of insanity would be actual lunatics. An absurdity like Christian Science is really "a sort of masked madness" (Maudsley)—it is the safety-valve which saves numbers of sufferers from the asylum.

344 Hudson street.

A NASAL CONDITION AFFECTING THE OCULAR MUSCLES.*

BY HEBER NELSON HOOPLE, M.D.,

OF NEW YORK, BOROUGH OF BROOKLYN;

SURGEON, EYE DEPARTMENT, WILLIAMSBURG HOSPITAL; CLINICAL ASSISTANT, NEW YORK EYE AND EAR INFIRMARY.

THE thesis I wish to advance is that faulty pressure within the nose can cause asthenopia of both the ciliary and external ocular muscles. To be more specific, I wish to show that mere mechanical pressure in a limited area of the nose, called by Mackenzie[1] the reflex area, can cause muscular asthenopia. By muscular asthenopia I mean impairment of the efficiency of the ocular muscles in the performance of their ordinary function.

The faulty pressure to which I refer is confined chiefly to the middle turbinate, but it may extend to the ethmoid cells, especially in cases of great hypertrophy of the middle turbinate. But I wish especially to point out that, without hypertrophy, where the middle turbinate is tightly compressed against the septum, or the septum is deflected against the middle turbinate, or a spur from the septum digs into the middle turbinate, or the middle turbinate is crowded by a deflected septum against the ethmoid cells, in all these instances we may have, and are almost certain to have sooner or later, muscular asthenopia

As a corollary to this claim, I would say that all cases, wherein muscular asthenopia is present as a result of the conditions just now enumerated, are equally likely to give the history of nasal headache, hemicrania, or migraine. As the pressure is not absolutely certain to produce the muscular disturbance, so it is not absolutely certain to cause the headaches; but, in about the same ratio as the one form of disturbance is produced, will the other also be brought about. It is not a part of my thesis to demonstrate the corollary; but, as the corollary is of great value to me, I wish to make use of it, and, fortunately for me, it has already been demonstrated.

Glasgow[2], Allen[3], Roe[4], Woolen[5], Pynchon[6], Loeb[7], Snow and others[2-4], who have investigated this offence of the middle turbinate, have made it evident by adequate inductive proof that the pressure and the headaches are correlates. They removed the pressure and, presto! the headaches disappeared—*sublata causa tollitur effectus.*

Patients suffering from such headaches seek the oculist in search of eye defects to account for them; they do not seek the rhinologist, because they have no symptoms pointing to a causative condition in the nose. It is in the study of just this class of cases that I have found the more or less constant presence of muscular asthenopia.

To prove my thesis one-half of the evidence is already in. I shall briefly summarize this before proceeding with other witnesses. The half that I refer to concerns the ciliary muscle; and as to this the following observers have reported, namely, Maxwell[8], Clark[9], Cheatham[10], Bettmann,[11] Hamilton[12], Gradle[13], Wood[14], Berger[15], Ziem[16], and Nieden[17]. They have all found cases of asthenopia whose cause was some form of local irritation in the nose on removal of which the asthenopia disappeared. Coincidence is not proof, but it is evidence. The evidence is cumulative. It has its value in support of my thesis so far as the local cause had its location in the specified area—the irritable or reflex area of the nose.

There is other evidence of the same character that is still more available for my purpose, be-

* Read by title before the seventh annual meeting of the American Laryngological, Rhinological and Otological Society, May 23, 1901.

cause it inculpates the external ocular muscles as well as the ciliary. It is furnished by De Schweinitz[18], Ziem[19], and Berger and Trymann[20].

In regard to the first group of witnesses, I will especially consider Maxwell's cases, some of whom were treated for nasal troubles as well as for asthenopia. It was noted that their asthenopia disappeared as soon as the nasal trouble was cured; and then the patients of their own accord threw aside their glasses without inconvenience. This would probably happen oftener in Maxwell's practice than it could in America. He very likely had to deal with but one kind of asthenopia, called by Gradle *normal* asthenopia, to distinguish it from another type which he called *excessive*. The former could tolerate without discomfort a small error of refraction. Seabrook[21], recognizing the same distinction, has employed for the second class of Gradle the well-chosen term *neurasthenopia*.

I purpose to avoid this second class and to present histories herewith of those alone that I regard as conforming to the normal type

Cases II. and IV. are given in the MEDICAL NEWS for April 13, 1901. Cases V. to VIII. are as follows:

Case V.—E—. E—, fifteen years old, schoolgirl; medium height, broad frame, plump, fat and heavy, well developed and well nourished. Rides a wheel. Appetite good. Menses regular; normal type. Yet she has frequent browaches, brought on by constant use of the eyes in study. Occipital headaches occasional, used to be more frequent. Some intolerance of light and excess of lacrimation on steady use of the eyes.

V. o. u. = $^{10}/_{10}$. Javal .50 c. a. 90°, with the rule

p. a. Ex. 4°, Ab 26°, Ad 31°. p. p. of Acc., o. d. 12 cm., o. s. 11 cm.

p. r. Es. 3°, Ab 4½°, Ad 17°. p. p. of Convg. 10 cm.

The left middle turbinate is tightly compressed against the septum. Instituted cold sponge baths every morning on rising. After two weeks at

p. a. Ex. 4°, Ab 10°, Ad 36°. p. p. of Acc. 10 cm.

p. r. Es. ½°, Ab 6°, Ad 18°. p. p. of Convg. 5 cm.

Divulsed the left middle turbinate vigorously and the right lightly and then tested again.

At p. a. Es. 6°, Ab 15°, Ad 29°. p. p. of Acc. o. d. 14 cm., o s. 16 cm.

p. r. Es. ½°, Ab 6½°, Ad 13°. p. p. of Convg. 7 cm.

Two days later the patient reports having slept soundly without the usual restlessness and tossing. She has had no headaches since the divulsion, though she has used her eyes constantly; there is no photophobia, nor excess of lacrimation.

At p. a. Eq., Ab 14°, Ad 41°. p. p. of Acc., o. u., 10 cm.

p. r. Es. 2°, Ab 6°, Ad 18°. p. p. of Convg. 7 cm.

This case is given solely to show the effect on the muscles, first, of the faulty compression, second, of the mechanical disturbance, third, of rest for forty-eight hours after the latter.

Case VI.—G—. P—, well-developed schoolgirl of fifteen years; 5 ft. 6 inches in height, weighs 120 pounds. Good appetite. Good general health. Menses regular. Sleeps enough and is rested by it; nevertheless, for the last three years she has been restless and has tossed in her sleep a good deal. This has been more marked during the last six months. She complains of blurring in reading, of twitching of the left eyelids and of headaches after prolonged study or writing.

V. o. u. = $^{9}/_{10}$. Javal o. d. 1.50 c. a. 90°, o. s. 1.00 c. a. 90°, with the rule. Exophoria ½°, Ab 5½°, Ad 15°. No hyperphoria. Acc. weak. Ordered + .50 c. a. 90°, o. u. to be worn till vacation. They were worn but vision was not clear with them, though better than without them.

Three and one-half months later, examined her eyes again under atropine. V. o. u. = $^{2}/_{10}$. Javal o. d. 1.50 c. a. 90°, o. s. 1.00 c. a. 90°. Found also H. o. u. 1.00 D.

Ordered, o. d. + .25 s ⌒ + 1.00 c. a. 90°.
o. s. + .25 s ⌒ + .50 c. a. 90°.

Three months later she reported relief of all the symptoms for which the glasses were given. Eleven months after her first visit she had a slight attack of grip. Six weeks later she came again with symptoms which she had had for more than a week. The left eye was heavy; the lid drooped; the left eye and brow ached; she felt as if she must keep that eye shut; both eyes were intolerant of light. Occipital pain occasionally. Tests with and without her correction both gave the same findings: Ex. ½°, Ab 6°, Ad 19°. At p. a.; Ex 18°.

The right middle turbinate touched the septum superiorly; the left was closely compressed against the septum throughout its entire surface. The patient has had a cough both this winter and last—a dry, hacking, ineffectual cough. The letters dance before her eyes in reading and her eyes are worse than they were a year ago when she first consulted me.

Two weeks later: She now complains of severe occipital pains. Cannot read longer than twenty minutes without troublesome dancing of the letters. Soon thereafter headaches set in.

In acc. at 10″, Ex. 18°, Ab 30°, Ad 30°.

At 20′, Ex. ½°, Ab 6½°, Ad 10°.

Owing to the narrowness and compressed character of the left naris, the left middle turbinate was removed as a whole.

Two days later: Her eyelids do not droop, although she continues to have pain over the left eye and in the occiput. But there is no blurring with her glasses, although the p.p. of Acc., o.d. is 25 cm., and o. s. 22 cm. Her p. p. of convg, however, is 5 cm.

In Acc., Ex. 18°, Ab 20°, Ad 28°.

At 20′, Eq., Ab 6½°, Ad 16°.

Eleven days later. She accommodates for No. I. J. at 12 cm. Ex. 6° to 20°, Ab 28°, Ad 23°.

At 20′, Ex. ½°, Ab 7°, Ad 17°. Rel. Acc. Neg. 4 D. Pos. 2.5°.

No further headache, blurring, nor intolerance of light. Holds both eyes wide open. Sleeps better. Has no more backache, as she had before at times.

One month later: She now complains that although the eyes have felt all right, yet each night on going to bed she has a face-ache on the left side. I find a remnant of the tubinate left in, closely pressed against the septum, and remove it.

Two weeks later: Patient now reports that she has been free from the face-ache ever since last piece was removed. No other symptoms.

p. a. Ex. 6°-16°, Ab 30°, Ad 46°. p. p. of Acc. 10 cm., o. u.

p. r. Eq., Ab 8½°, Ad 35°. p. p. of Convg. 6 cm.

With the aid of the weighted convergence stimulus she carries 42° of adductive prisms to 20′ and raises it to 65°.

The salient points in this case are these: The patient is a strong, healthy girl; has had restless sleep for three years; has symptoms of accommodative asthenopia and occipital headaches. There is exophoria; there is also weak abduction and weak convergence. She is given her correction for hyperopic astigmatism which she wears for nine months and then has the grip. Three months after that the left middle tubinate is removed and a month later a pressing remnant of the same. Since then all her symptoms are gone. She has now restful sleep. She reads continuously without discomfort. Her cough is gone. Accommodation and convergence are now good. The muscles all give strong tests and good balance except at the near point, where there is merely a lessened exophoria. The touching right turbinate is left severely alone, because there are no symptoms.

Case VII.—Miss M— C— D—, twenty-three years of age. In good health. Puts on flesh and maintains good nutrition. She is wretched with very severe headaches, throbbing at times, which are becoming more severe and frequent. She has had them for many years. They extend from the right side of her forehead to the temple, vertex and occiput. Sleep often relieves them; but sometimes she cannot sleep on account of them, they disturb her whole night and she rises with them the next morning. Her menses are regular, but painful. Her eyes burn. She has conjunctivitis. She has had styes. There is no special tenderness of the trochlear or supra-orbital nerves. V = $^{10}/_{10}$ with each eye. There is the merest trace of vertical astigmatism. She has Hm.+.50s. Ophthalmoscope measures ×1.50s, o. u. She reads No. I. J. comfortably with or without +.75s.

At p.a. Ex. 9°. At 20′, Ex. 2°, Ab 4½°, Ad 12°.

Her left nostril is normal. Her right has a long shelf on the septum almost occluding the inferior meatus and the right middle turbinal is tightly compressed against the septum.

On February 21, 1901, this nostril was relieved of its ecchondrosis and its offending middle turbinal. The extent of surface disturbed caused tedious recovery. But, exactly one month later this patient reported that she had slept so soundly she had not heard the breakfast bell, a most unheard of occurrence with her. She has had no headaches. Menstruation occurred in the interim and was painless for the first time.

April 23, 1901. At p.a. Ex. 4°, Ab 23°, Ad 41°. At 20′, Es. ½°, Ab 5°, Ad 65°. p.p. of Acc. o.d. 9 cm., o. s. 8 cm. p.p. of convgce. 7 cm.

A new experience with her is to be able to shop all day long without a headache. She is an inveterate reader and has been reading many books during this last month without any discomfort. I have given her no glasses for her hyperopia; she does not seem to need them. If she were to have her correction, doubtless her eye-muscles would give even a better account of themselves. But, *cui bono?* She is perfectly comfortable as she is. This case has an argument in it for those who say that ametropia is the sole cause of asthenopia.

Case VIII.—Miss E—— M——, twenty-seven years of age. Stenographer. Woman of solid build and sturdy endurance. Likes work and does not tire at it. She has been wearing for two years, o. u. + .75 c. a. 90°, given her on account of pain in the eyes recurring daily.

Present symptoms: Headaches frequent for the last six months, occasionally very severe, extending along the right side of the head to the occiput. She has noticed blurring in her right eye, especially at the onset of her headaches, which are severe enough to drive her home from her work.

V. o. u. = $^{10}/_{10}$. Javal 1.00 @ 90°. Media clear. Fundus normal. In Acc. Ex. 8°, Ab 30°, Ad 20°. p. p. of Convgce. 12 cm.

At p. r. Ex. ½°, Ab 4½°, Ad 15°. No hyperphoria.

Right middle turbinate closely compressed against the septum; left middle turbinate touches the septum more lightly. Divulsed both middle turbinates. After a month and a half with frequent tests in the interim, the following findings were obtained, associated with return of slight blurring in right eye, though headaches had been banished together with an irresistible desire to close the eyes in church.

In Acc. Ex. 6°, Ab 25°, Ad 16°. p. p. of Acc. o. d. 13 cm, o. s. 10 cm.

At 20′ Es. ½°, Ab 6½°, Ad 31°. p. p. of Convgce. 12 cm.

I found the right middle turbinate still no better for the attempt at divulsion and felt compelled to remove it, as the blurring continued and the patient was unwilling to let the treatment go at that. if the condition could be bettered. This turbinate was removed after which there was some nausea and pain in the right eye for forty-eight hours. Blurring and photophobia to some extent continued in the right eye for ten days, after which her tests were as follows:

At p. a. Es. 2°, Ab 26°, Ad 31°. p. p. of Acc. o. u. 10 cm.

At p. r. Es. 7°, Ab 6°, Ad 8°.

Improvement kept up daily. Blurring went away. In two weeks,

At p. a. Ex. 5°, Ab 24°, Ad 25°. p. p. of Acc. o. d. 10 cm. o. s. 9 cm.

At p. r. Es. 1°, Ab 6°, Ad 34°. p. p. of Convgce 11 cm.

Histories of cases belonging to the neurasthenic class also show improvement following proper attention to the same faulty condition. In these cases, however, I am loth to interfere radically; and I do so only upon the urgency of the patient's need of relief of most distressing symptoms, *i. e.,* when the asthenopia and headaches are both extreme.

When the removal of the whole of the middle turbinate is thought necessary, it is approached with great hesitation and circumspection. It is no light matter to deprive the nose of so important a functionary. Delevan[22] has pointed out a most scientific reason for its partial or complete removal. He found, by examination of the Hyett collection of skulls in the College of Physicians of Philadelphia, "in nearly every instance in which hypertrophy was observed it was confined to the middle turbinate bone of the wider naris." Operation for deflection would fail of its object without first removing a part, or the whole, of this hypertrophied body. After this, and not before, he would straighten the septum, and in this he is supported by Zuckerkandl.[23] I am able to add another reason to those which he has given. I have found in such a case that the hypertrophied middle turbinate was the cause of a concomitant asthenopia which was sufficient of itself to call for its reduction or removal, before returning the septum to its normal place. But, where conservative surgery can save the body of the turbinate, it should be saved. Pynchon's guarded trephine is useful to this end.

In the study of these and of other cases not yet reported I believe I have grounds for making the following postulate: A moderate amount of pressure or mechanical irritation of the middle turbinate and adjacent septum will temporarily impair the function of the ciliary muscle. To a less, or more variable, extent it will also impair that of the external ocular muscles. I have repeated this observation many times when giving to patients that mechanical treatment necessary to relieve such pressure. Now, if mechanical irritation for a brief period can impair the function of these muscles, how much more would a continuous pressure irritation of that same area keep up that impairment! It is such continuous pressure that is produced by a spur, or bend in the septum when it digs into a too-closely-applied middle turbinate.

I do not look upon the headaches in these cases as in any way a symptom of the asthenopia; they are but frequent associates, yet, they are often inseparable. The reason for this must be evident. They have a common cause, pressure on the same sensori-motor branches of the fifth nerve. So far as the sensory part is affected a radiated or a reflex headache is produced; so far as the sympathetic fibers are affected a vasomotor reflex is produced. This is equally true where there are inflammatory conditions, as in ethmoiditis. It matters little whether the pressure is from *within* the ethmoid cells and turbinate, or is applied to these from *without.* The important point is that the same branches of these nerves are the nerve elements pressed upon and therefore the same kind of disturbances should be expected to follow.

Not *pain,* but *tire* is the expression of sustained and exhaustive effort by weak or inharmoniously acting muscles. If pain ensues, it is secondary and not the direct result of effort. The only part which vasomotor nerves can take in producing pain is to increase the blood-supply to a sensitive area and thus increase its susceptibility. The asthenopic disturbance is probably from the sympathetic fibers in this particular class of cases. That it is such in all cases is also probable. It could properly be inferred from other facts, as, *e. g.,* when treatment addressed to the uterus, the bladder, or the stomach in other cases, has given relief of the asthenopic symptoms. The only thing conceivable as being common to all these varied causes is the element of the sympathetic nerves. In conclusion, I have only this to say by way of harmonizing the various facts, practices and theories, that I expect to see the time arrive when muscular asthenopia will be recognized as but a symptom of disturbance of a part of the sympathetic nervous system.

CRIMINALS AND DEFECTIVES: HOW BEST TO REDUCE THEIR NUMBERS.

BY J. C. MC CASSEY, M.A., M.D.,

OF DAYTON, OHIO.

UPON the solution of this problem rests the welfare of home, nation and civilization. The proper study of mankind is man. At the dawn of the new century the United States finds itself confronted with an alarming increase of crime. During the past fifteen years the population of the

United States has increased 25 per cent., but during the same period crime has increased 60 per cent. During this period crime has markedly decreased in the British Dominions in proportion to the population. This increase in our criminals and defectives is a sore spot in our political and social system. No one can afford to ignore this subject. It concerns every taxpayer, and every one who makes his own living is a taxpayer, whether he owns real estate or not. The politicians and ward-heelers have virtually had charge of the criminals and defectives. It is time the physician should be called in to diagnose the disease, and proclaim to the world that crime and defectiveness are due to neglected education, heredity and disease. The wardens of penitentiaries and executive officers of reformatories should be physicians. The law as administered at present is intended for normal beings and not the criminal, who is an abnormal being. Careful and scientific treatment must be substituted for a political sport's system of management. Laws should be directed toward the criminal and not the crime. The basic causes of crime must be attacked. The remedy consists of prevention, reformation and education.

It is wise for a growing nation, like a growing boy, to consult a physician with regard to its health. The physician will prescribe and direct the following: Intelligence is the lever capable of raising mankind. Through it, we begin the conquest of ignorance, poverty and crime. The preacher, priest and hangman have failed to stay the rising tide of vice and crime. Ignorance, poverty and vice must stop populating the world. To this end woman must be taught to become mistress of herself and decide for herself whether she will or will not become a mother. Then the babes that are born will be welcome. They will fill homes with light and joy. People unable to support themselves fill the tenements, the huts, and the hovels with children. They depend on the Lord, on luck and on charity.

According to vital statistics it takes on an average about 3½ children to each couple to propagate their kind. Too many people are heedless of all Biblical commands except to "multiply and replenish the earth." More children have been borne to poor people than they can rear properly, whereas parents of education and means rarely have more than two children. If they have a third child, it is a mistake. This disparity is a cause of the lack of growth of the population at the top and of an excessive growth of the population at the bottom.

The man-made laws have accorded the male sex dominion over the female, which has placed millions of girls and women at a disadvantage in the struggle for bread, and which compels thousands of them yearly to accept degradation or starvation. The slur that is becoming affixed to "stenographer and typewriter" is familiar to many. One lady while seeking a position as a stenographer and typewriter was asked so often by those seeking her services, if she would be "accommodating" that she gave up the business for that of a trained nurse. *The Arena* for January, 1898, gives the following figures for Massachusetts, New York and Illinois: 16 per cent. of married men desert their first wives after the birth of their first child, and 28 per cent. after the birth of their second child. Women have opened their eyes to this condition, and as a result 18 per cent. of women of marriageable age in the United States have equipped themselves for earning a living independent of man. Thus, she was forced to take his position in manufacturing, mercantile, professional and other pursuits. The failure of husbands to provide for their wives cost them their jobs in many cases. The helpless slavery of woman with the attendant evils of enforced motherhood must be relegated to the rear as a crumbling relic of barbaric injustice.

If the father is the head and hands of the family, the mother is the heart.

Schools in Relation to Crime.—The intelligent taxpayers are compelled to take cognizance of the school question and the criminal problem in self-defence. It is more economical for taxpayers to support the kindergarten and the industrial schools, and thus teach the rising generation how to be self-supporting, than it is for them to maintain a great army of criminals and defectives. Many people go to prison because they have never learned how to earn an honest living. Manual training in our schools should be multiplied, skilled workmen of good character need not go long looking for work. It is the unskilled pretenders of questionable character that compose the swarming job-hunters. The men and women that come to the Friendly Inn expressing a willingness to do any kind of work, do their work so poorly and slovenly that in most cases it is economy to let them sit idle rather than allow them to spoil material. It is found that the higher the character of the daily pursuits in life the greater the unlikelihood of falling into crime. Criminals as a rule are only accustomed to the crudest forms of labor.

There is a false notion that university degrees for women will impair their usefulness as housekeepers or wives. The fact is university degrees to-day would be more useful to the nation among mothers than among female teachers. The female college graduates need not apologize to the world for their interest in learning. The better education a woman has the better she is fitted for motherhood. Both men and women in the household are governed by their hearts and not their heads. A man with a university degree does not neglect his children. College training does not unfit a woman for domestic duties. John Wesley's mother had a college training. She directed the education of her family, which reflected great honor upon her. The mother who can teach her children and direct their reading will command higher respect and love from them than the mother who is ignorant, however amiable. Let us give more instruction in cooking and

domestic economy, dignify this kind of knowledge and graduate good housewives rather than novel-readers, house-ornaments and factory-girls. To-day women who abhor cooking, mopping and general housework can be found in swarming myriads. Many women fitted by Nature to bring up children have their lives blighted by grappling with the dead languages or biology. The only valuable education is that which enables a person to make his or her way in the world.

Financial Standing.—This takes too high a rank over virtue and morality. It dominates the marts of trade and dictates the courtesies of the street, formulates the laws of fashion and times the chime of the marriage bells. Its voice is heard in the music of the choir and on the cushion of the pew. Everywhere the dollar sign is traced in threads of gold. Even the church and its moral forces falter to stem the tide and cringingly bow to the overmastering powers of wealth. We are all under the ban and have our shortcomings. It is said that if the least of the sins of the best of us were written across our foreheads, we would walk the streets with our hats pulled down.

Division of the Vicious Circle and the Saloon in Relation to Crime.—Eighty per cent. of drunkenness is due to heredity; alcohol causes 33 per cent of all diseases, 75 per cent. of the crimes, and 50 per cent. of the poverty that afflict our race. Intemperance of parents causes 34 per cent. of the imbecility in children. The general causes of insanity are: heredity, 50 to 60 per cent.; whisky, 12 per cent.; religious perversion, 10 per cent.; disappointment in love, 10 per cent.; financial embarrassment, 5 per cent. Crime, imbecility and insanity are due in 50 to 75 per cent. of cases to heredity; 50 per cent. of criminals are inebriates; 20 to 25 per cent. of criminals are born criminals. Three-fourths of the crime in our land is caused by neglecting education. Three-fourths of the crimes are committed by habitual criminals. Only 10 per cent. of the criminal offenses are detected and punished.

During the past year the corn crop in the United States was valued at seven hundred and fifty million dollars; cotton, three hundred and fifty million; wheat, three hundred and twenty-five million; oats, two hundred million; potatoes, one hundred million dollars. The amount paid last year for liquor consumed in the United States was one billion, one hundred and seventy million dollars, or an amount greater than the corn, cotton and wheat crop of the whole country. The only items that rose higher in value were the exports in general merchandise, $1,400,000,000, and income from railway service, $1,200,000,000 (Official Revenue Report).

It is found that 31 gallons of beer contains the same nourishment as one loaf of bread. The saloon is the home and resort of the criminal. It is the place where he spends the money obtained by crime. It is the place where he meditates on crime. Dram-drinking is not an offense against property. The drinker pays his money and takes his drink. If he is violating the laws of the land there is no one to complain. The offense is against society as a whole. In the case of housebreaking or theft there is no difficulty in finding the plaintiff, because he is interested in recovering damages or goods. The saloon is such a powerful factor in our political system that it seems to be impossible to get legislators to enact laws to regulate this great traffic. The saloons should be owned and run by the government. This would eliminate private gain. They should be run on the same plan as the post office.

Characteristics of Criminals.—The physical and moral characteristics of criminals are not so valuable in convicting them of crime as in classification and treatment. A person may have insane ancestry and be inevitably doomed to insanity; yet his liberty cannot be abridged without some warrant from his action or words. Also, a person may have many of the essential characteristics of a criminal, and through favorable environment he may pass through life as an upright citizen. The characteristics that are of interest and value are as follows:

The great bulk of criminal heads are of average size, but small and large heads predominate. Thieves more frequently have small heads and murderers large ones. While there is a lack of symmetry in nearly all heads, this is one of the most constant features of criminal skulls. The weight of the brain is not of importance. The shape and relative development are of more value. In criminals the weight of the cerebrum is above the normal average. Confluent fissures are found in the brains of criminals and idiots with more than ordinary frequency (Benedict). There are fewer convolutions in the brains of most criminals than in ordinary brains (Flesch). Meningitis has been found in 50 per cent. of criminals (Lombroso). The writer made autopsies on 50 insane criminals and in 29 cases found meningitis and more or less atrophy of the brain. In one case a colored patient, who was committed to the penitentiary for murder, refused to eat and was transferred to the Insane Asylum at Topeka, Kas., where he died six months later. An autopsy revealed meningitis and complete occlusion of the superior longitudinal sinus with inflammatory products. A patient whose case was in the courts of Atchison, Kan., for two years for the alleged crime of rape was finally acquitted of the crime, but was adjudged insane and sent to the asylum. When he died an autopsy revealed meningitis and atrophy of the upper part of both hemispheres of the brain.

From an examination of a large part of cases and autopsies on a considerable number, the writer is convinced that a large number of patients are erroneously sent to the State prison instead of to a hospital for the insane. Heart disease is found in 20 per cent. of criminals. Syphilis causes gummatous tumors in the brain and otherwise impairs the mental function and thus causes crime. Tuberculosis, owing to toxins circulating in the brain leads to crime. High

cheek-bones go with strong animal passions. Criminals usually have the lower jaw unusually developed. The ears are outstanding, the nose is crooked and has a poor bony framework. The skin is dark and pale; wrinkles appear prematurely about the mouth and nose and not in the forehead, as in profound thinkers. The assassin has animal eyes, usually eyes like a cat's eyes. Criminals are frequently left-handed, have tendon reflexes absent or exaggerated, great acuteness of vision, but defects in hearing, taste and smell. In them wounds heal rapidly, as in the crude races, such as the Egyptians and the Chinese. Criminals are usually flatfooted and below the average height and weight, and have deficient muscular development. Beautiful faces are rarely found among criminals. They are incapable of blushing. Thieves usually have great mobility of their features and hands. Their eyes are dark, small and restless, the eyebrows thick and close, the forehead usually narrow and receding. In the sexual offender the eyes are nearly always bright, the voice rough or cracked. The face is generally delicate, except the jaws, which are usually heavy. The lips and eyelids appear swollen. The homicide usually has a large beaked nose suggestive of a bird of prey and his eyes are glassy, cold and fixed. The sharper and forger, in order to inspire confidence, puts on an angelic face and a clerical appearance. In criminals, as a rule, the beard is scanty, the hair dark, abundant, long, and often wooly; baldness and gray hair are rare among them, but frequent among the insane, the business and professional man. Gray hair appears early in criminal women. Women guilty of infanticide usually have an excess of hair on the face. Eleven per cent. of idiots have continuous eyebrows. Among criminals dark hair predominates, except as regards sexual offenders, in whom fair hair abounds and the prevailing color is reddish. Red hair is infrequent among born criminals, but abundant among the insane and sexual offenders. Fair and redhaired persons are susceptible to fevers and zymotic diseases. The brightly pigmented persons with sensitive vascular system will soon be eliminated from the criminal calendar.

The crimes of women are generally due to emotional causes; as love, jealousy, hate, revenge, vanity, etc., because woman's emotional nature has been more highly developed. Women persist in crime more than men, because of the greater social ostracism of degraded women. Women endure pain and privation better than men, and therefore do not take to crime from want so readily as men. Women are more cruel than men, but criminal women are usually masculine. Females, being physically weaker than males, are addicted to crime only one-fifth as frequently and only excel the males in the commission of poisoning and infanticide. Woman's natural form of retrogression is prostitution. This is why there are no female tramps.

Even children readily form likes and dislikes for persons they meet. They have an intuitive knowledge of strangers. In the child, up to a certain age, are manifested the saddest tendencies of the criminal. Even infants at the age of two to twelve months manifest anger and rage and will strike at nurses and break dishes (Lombroso). Stanley Hall says all children are liars. The Psalmist, said in his haste, that all men are liars, and were he living to-day he could say this with deliberation. Children are too often induced by fraud and ruse to do things they dislike. Thus lessons in deception are learned. The child may prefer wrong to right, because the true moral sense is wanting. Many never pass from this to the higher plane. National education should be empowered to classify children according to their moral sense as well as their intellect. One corrupt pupil may infect the whole school. Those feeble in morals and intellect should have extra guidance and instruction. The idea of goodness should be held up, rather than that of badness. The way to destroy evil is not to hold up and analyze it in order to make it hateful, but rather to let it pass out of consciousness.

The subject of criminology has in store rich rewards for its students. Our knowledge of the subject to-day is but as droppings before the shower. The law of disease is as beautiful as the law of life. In the law of disease the line of progression is reversed. The born criminal is a moral monstrosity cast upon the shores of the present by the receding waves of barbarism. Savages drink blood before engaging in conflict. Many dwellers in civilization to-day become engaged in law-breaking and conflict after drinking whiskey. Mobs are incited to frenzy at the flow of blood and crowds catch the infection.

Crime occurs in epidemics under the inspiration of examples suggested and published in the newspapers, especially if the perpetrators escape detection.

The born criminal invariably has physical signs of degeneracy. They are akin to the victims of moral insanity. He is usually free from small vices, and often possesses considerable intellectual ability. He asserts that he cannot afford to drink for fear of impairing his skill in his craft. His language is slangy. He plots against the rich, he is always against the government, and he is unpatriotic. He may be religious. He lacks curiosity, the fundamental element in progressive education. He is insensible to pain, which is the cause of his cruelty. He can undergo surgical operations without an anesthetic. He lacks remorse. This is a sure sign of incurability. His lack of remorse and conscience accounts for the apparent sincerity with which guilt is denied and the equanimity with which he meets his doom. He is lacking in foresight and in the imaginative faculty, consequently no warning signals light for him the pathway of hidden danger. This is why he faces futurity with unconcern. Where this faculty is highly developed, it makes cowards of us all. The born criminal is notoriously untruthful, incapable of blushing, full of vanity and often exaggerates his crimes on this account.

Holmes confessed to crimes of which he was not guilty. The criminal by passion has no criminal characteristics and shows remorse for wrong-doing. He does not commit crimes against property. He is not a permanent enemy to society. He is simply lacking in self-control and accepts discipline and correction with advantage to himself and all concerned. The criminal from moral cowardice commits a small wrong, and, being lacking in sufficient moral courage to face the world and live it down, commits a greater crime in order to cover it up. Frantz of Dayton, Ohio, the slayer of Bessie Little, and Jackson and Walling, who beheaded Pearl Bryan, are examples.

Police System.—Frequently the police patrol is seen crashing through the streets at top speed as if life depended upon it; nine times out of ten the noise and crash over the cobble stones fails to arouse the captive from his drunken stupor. No high-grade skill is necessary to capture such victims and no great good is accomplished, except temporary removal of a nuisance. During the past years height, avoirdupois and political pull were the prerequisites for a position on the police force. The police tried to see as little wrong-doing as possible. They closed their eyes to glaring obliquities and the things they were paid to detect and correct. But since civil-service examinations are required great improvements in this system may be expected. I would go still further and fill all vacancies on the police force with high-school graduates or those holding certificates to teach in the county with the addition of requirements of a civil-service examination. This would create a demand for more highly educated people and cause an upward tendency in education. The police should be the guardians of morals of the people, should teach them to obey the law; be the supervisors of the children on the streets. The salaries of policemen range from $60 to $80 per month. High-school graduates and male teachers are begging for positions at $40 and $50 per month. Patrolling the beat is less confining and more healthful than teaching school. There would be no difficulty in filling the vacancies in the police force by well-educated men of good character.

Our population has 20 per cent. of foreigners in it, but they furnish more than half the inmates of our reformatories, one-third of our convicts and three-fourths of the paupers (F. H. Wine, Eleventh Census). The negro was transplanted on American soil against his will by the whites and kept in slavery 260 years. The negro forms 12 per cent. of the population of the United States, commits 32 per cent. of the crimes; contributes 8 per cent. of the paupers and only 5 per cent. of the lunatics.

Another cause of crime and pauperism is the undue flocking of the urban population to the cities.

The spoils system and political management of our jails and prisons make these institutions high schools of depravity. Then we have homicide for life insurance, which came with the advance of civilization; also the abuse of cocaine, opium and the other narcotics. The false representations and the false teachings of the tragedies of Shakespeare and other authors help to swell the lists of crimes on the calendar. Disobedience to the laws of Nature and physical hygiene during the present or preceding generations is found to be the main cause of crime, defects and disease. From the cradle to the grave, man is in constant danger from the effects of violated laws.

The Death Penalty.—The death penalty is in force for murder in all the States except Rhode Island, Michigan and Wisconsin. In 1874 capital punishment was abolished in Switzerland, the Cantons were permitted to restore it in 1879, but up to 1890 no Canton had done so. The death penalty was abolished in Holland in 1870, in Italy in 1889, and in Portugal in 1867. Capital punishment for ordinary homicides has been abolished in Russia for over a century, although it is still the punishment for treason. The general testimony is that there has been no increase of murder in those countries since such abolition. Where the penalty for murder is death the prisoner has many more chances to escape conviction than if the sentence is life imprisonment. There is a small percentage of convictions for murder compared with the number arraigned for murder. The death penalty is a crumbling relic of barbarism. It cost the State about $20,000 to try Durant; $20,000 to try Jackson and Walling; $25,000 to try Luetgert; $20,000 to try Frantz. The cost to the State for trying an alleged murder, if put on interest, would keep a person a whole lifetime in comparative luxury.

Remedy.—It is more economical to put forth every effort to prevent the formation of bad habits in the young than to try to reform confirmed transgressors.

The average length of sentences, including life sentences, is only two years, while the average confinement in insane asylums is four years.

The board of pardons should consist of sentencing judges, the warden of the prison, and one of the chief justices of the State. This board should meet quarterly, hear evidence and correct mistakes of sentence.

The issuing of marriage licenses should be restricted by a national law requiring medical and other certificates to be filed with the Probate Court, showing that the applicants for marriage licenses are free from insanity, criminality and other hereditary taints.

For the cure of the social evil the following prescription is offered: Extension of manual education and industrial schools; improvement in motherhood; stop lease system; extension of reformatory plan; adopt intermediate sentence; improvement in jails; extension of probation system, both for youths and adults, as in Massachusetts; work for prisoners even on short sentences and allowing them a portion of their earnings to be sent to their homes or families. Abolition of spoils system in prison management; higher grade of prison officers; physicians should

be wardens of penitentiary and executive officers of reformatories.

The physician, being armed with the chemical laboratory, the X-rays and other modern means of scientific investigation, will naturally become the mentor of the people, and, as he now protects our shores and municipalities from pestilence and infectious diseases, he will also protect society from crime.

MEDICAL PROGRESS.

Organic Preparations of Iron.—JOLLES (*Wiener med. Bl.*, June 27, 1901) insists upon a classification of these preparations from a chemical standpoint. It is important to know whether a given preparation is an acid or an alkali-albuminate. In chlorosis and anemia the acid of the gastric juice is diminished. If in these conditions an alkali-albuminate be given, a combination is formed with the slight amount of acid present in the stomach and an increase of digestive disturbance results. On the other hand, acid-albumins containing iron make no hurtful demands on the weakened stomach and reach the intestine unchanged, ready for absorption. Fersan is an acid-albumin containing iron and phosphorus and is a type of the preparations which the author considers to be indicated in anemias.

New Phimosis Operation.—H. S. SCHLOFFER (*Centralbl. f. Chir.*, 1901, No. 26) states that true circumcision deprives the glans penis of its normal covering and later of its normal sensitiveness, and that the dorsal-incision method causes two unsightly and often unmanageable flaps. Phimosis can be cured without going to either extreme of inconvenience and still with entire satisfaction by the method devised by him and successfully employed for over a year. In the marked cases the ring causing the phimosis is cut a very short distance in the mid-dorsal line. After the skin is stretched evenly and firmly backward toward the base of the organ and held in that position, the *outer layer*, consisting of the skin only, is divided in a straight line with the knife obliquely to the right from the mid-dorsal line outward and backward till a point corresponding with the corona glandis is reached. The degree of obliquity of this cut depends entirely upon the degree of the phimosis. In the marked cases the end of this cut may end over the lower quadrant of the organ. Then the skin next the glans is cut toward the left from the midline outward at the point where the first cut began to the same length and amount of obliquity. When the foreskin is retracted gently a rhombus is formed by the two cuts. By placing a tenaculum in each of two diagonally opposite corners and pulling, it may be elongated according to needs and brought to lie transversely over the sulcus. The tension on the underlying connective tissue must be relieved by dividing it down to the tunica albuginea. The opposite long sides of the parallelogram are then sutured each to each, thus adding its length to the circumference of the original opening in the prepuce. When the foreskin is reduced to its normal position one-half the sutures are hidden against the glans and a free, cosmetically pleasing opening is produced and the foreskin is left to ensheath and protect the glans penis and its sensitiveness.

Ligation of the External Carotid.—W. W. KEEN (*Annals of Surg.*, July, 1901) reports two cases of severe hemorrhage, threatening life, one after tonsillotomy and the other after a slight intranasal operation, in which life was saved by ligation of the external carotid after the patients were very much blanched by the loss of blood. In one patient a tonsillotomy wound had continued to ooze rapidly notwithstanding all efforts to check it. In the second patient some apparently insignificant nasal growths had been curetted from the septum, but persistent bleeding was set up which nearly ended the patient's life. The fear which most surgeons have, that the wound which is necessary for the tying of the artery will in its turn be a bleeding area and continue or even aggravate the hemorrhage one is aiming to stop, Keen states is probably groundless. In these patients the artery was found and ligated in a very few moments and the incision closed by primary union without material bleeding at any time. As the hemorrhage at the original operation sites stopped almost at once and was permanently controlled by the procedure, he concludes that the little operation should be performed whenever such accidents occur. The one precaution of the treatment is to be certain that the external and not the internal carotid is tied. The latter unpardonable blunder is always fraught with damage, more or less pronounced and prolonged, to the cerebral substance.

Pruritus Vulvæ.—L. SIEBOURG (*Centralbl. f. Gyn.*, 1901, No. 26) makes the following contribution on the treatment of this vexatious and persistent condition. It was suggested by the fact that often after a copious subcutaneous injection of normal salt solution the skin will remain for several days either deprived of sensation or with depressed sensation. He does not mean to imply that all his cases are subjected to this treatment. He ordinarily manages them by having the cause fully removed

when possible, for example, acrid vaginal and uterine discharges, diabetes, cystitis, foul pessaries, pudendal vermin, etc. When the cause has been ascertained and removed he finds that ordinarily the itching disappears, but sometimes the patients are so nervous and irritated by their former trouble that the injured skin continues to irritate and a pruritus which ought to have vanished with its cause is maintained. For such cases he finds good hygiene, as to food, exercise, sleep, baths, coitus and douches, of great importance. Then resort may be had to some lotion producing local anesthesia, for example, one containing cocaine, menthol and phenol. Several ointments are of signal use even if the skin and mucosa are broken. His favorite is cocaine 2, menthol 5, phenol 1, vaselin 20 parts, spread upon gauze and held tightly in place with a T-bandage. In the more chronic cases he has the patient paint the parts with a mixture containing spir. rusci 50, acid. salicyl. 5, resorcin 1 part, night and morning. When these means have failed he uses injections of copious quantities of normal salt solution until the vulva is much swollen in both the skin and mucous aspects. The idea is to rupture by distention, if possible, the fine nerve filaments and thus destroy the itching. Various medicaments might be added, but the simple saline solution is the least dangerous. His success has up to the present time been very marked.

Pseudarthrosis.—F. COLLEY (*Centralbl. f. Chir.*, 1901, No. 26) relates a successful treatment of a case of pseudarthrosis of both bones of the forearm following a simple complete fracture due to very slight trauma. The comparative insignificance of the injury, together with the failure of any union after all the ordinary means of treatment had been diligently tried, suggested the possibility of a pathological fracture due to some neoplasm. An exploration and microscopical examination resulted negatively on this point, but not the slightest callus could be detected. Severe delirium tremens now set in, which forbade the undertaking of any bone suture. While maintaining the fragments in the best possible apposition with splints, he thought of irritation of the bone ends. For this purpose he used the method originally suggested by Arthur Barth, namely, bone ashes. He took femora of beeves and reduced them to ashes which he pulverized and then rendered sterile by heat. This mass he suspended in a mixture of gum arabic and water which was also sterilized by boiling. Finally a thin fluid mass was obtained which could be forced slowly through a large size syringe. Through his original exploratory wound he injected 10 c.c. every four weeks and succeeded in producing the desired results, first irritation, then callus-formation and, finally, ossification. He has been so pleased with his cure, which a year after the experiment is still good, that he has undertaken a long series of observations among animals, the net results of which will be published in full at a later date.

Castration For Tuberculous Testes.—VON BRUNS (*Arch. f. klin. Chir.*, B. 63, H. 4) states that the ultimate results of castration, unilateral and bilateral, for tuberculosis of the testicles are a matter of great importance and have long been an object of dispute. As a contribution toward the settlement of this question, he went through the records during the past fifty years at the clinic in Tübingen and gives the following conclusions. As to whether the whole testis or the epididymis and whether one or both organs should be removed, he sums up the arguments as follows: The removal of the entire testis is often unnecessary, because the epididymis is usually the first and only part to be involved. Therefore, with an early diagnosis it is sufficient to remove only the evident foci of the disease. Castration on one side is not justifiable, because the other elements of the genito-urinary tract are so often involved as to render its result null. This depends entirely upon the theory that testicular tuberculosis is a disease descending from one of the upper genito-urinary viscera. As a matter of fact, there is nothing to prevent the focus being primarily and simply testicular and later, by ascending involvement, attack the seminal vesicles, prostate, bladder, ureters and kidneys. Double castration should always be avoided, first, because when both testicles are attacked the rest of the tract is also involved, and, second, because of the psychical and moral effect upon the man. In support or destruction of these contentions he collected 111 cases with a subsequent history of each up to the limit of thirty-four years after the operation. Of these 78 were unilateral, 33 bilateral true castrations, *i.e.*, without attack upon the seminal vesicles or prostate. As to the progress of tuberculosis of the epididymis into the main testis, he found that within two months 18 per cent., three months 24 per cent., six months 40 per cent., and later than six months 60 per cent. of the testes had become diseased. Hence, within the first half-year nearly half of all cases have suffered extension and removal of the epididymis is only half the work. In his series of cases he finds 38 per cent. bilateral in their disease. Of these 23 per cent. had been castrated on one side and later had the other break down. As to the final prognosis, he elicited that 12 per cent. died of genito-urinary tuberculosis, 15 per cent. of pulmonary and other tuberculous disease. Of these the great majority were so diseased before the operation. Further, in 26 per cent. the second testis broke down. Of the cures he finds 46 per cent. permanent and the duration varied from three to thirty-four years. Such are the records for the unilateral castration. For the bilateral operation, about the same proportion died of genito-urinary disease, 15 per cent., 25 per cent., of scattered tuberculosis, while 56 per cent. show cures locally enduring from three to thirty years as the possibility of the second testis breaking down is, of course, expunged by the operation. No single case of insanity occurred. Of the total just 50 per cent. were cured for the balance of life. In

general death ensues in all who have tuberculous processes higher in the genito-urinary tract or elsewhere in the body.

Mammary Cancer.—W. L. RODMAN *(Annals of Surgery,* July, 1901) states that for the best results of removal of cancers of the mammary gland the following practical points must be observed. Not only the entire gland, but also all the adjacent supernumerary masses of glandular tissue must be removed, because these likewise have a tendency to a marked degree to become cancerous. Operative convenience and good sense require that the gland be dissected off from the upper regions downward, clearing Morenheim's space and axilla at the same time, and from the sternum outward. The skin incision must be very free so as to embrace all of the skin covering the gland. Both the pectoral muscles and the fascia overlying the intercostal muscles should be removed at the same time. In young women cancer is apt to follow a very active and short course. Hence all doubtful cases must be carefully investigated pathologically before the whole gland is sacrificed. In order to secure the best results of a total ablation of the mammary gland as to the primary healing of the wound he finds that Warren's incision is the best. The special feature of this method is that an inverted Y-shaped incision joins the posterior sweep of the main cut and a vertical straight one meets the anterior sweep over the subclavicular space. By undermining, the four flaps thus created can usually be brought into apposition and commonly primary union ensues and the patient is discharged in ten or twelve days.

Wounds of the Venous Sinuses.—H. R. WHARTON *(Annals of Surgery,* July, 1901) gives an analysis of seventy-five cases of wounds of the venous sinuses of the brain and makes the following deductions: (1) Wounds of the venous sinuses should be classed as among the more serious injuries, being followed by a high mortality from both extra- and intracranial hemorrhage and from infection; (2) they are especially liable to infection resulting in septic thrombus and pyemia; therefore, the greatest care must be exercised to render them aseptic and to keep them so; (3) the most satisfactory and usually aseptic method in controlling the bleeding is by gauze packing; (4) ligation of the venous sinuses is a procedure of peculiar and definite difficulties which prevent its employment except in those free wounds where the sinus is fully exposed and forbid its application in the ordinary accidents to the sinuses; (5) the tying of lateral ligature upon a sinus is much easier and less dangerous, but is available only in small wounds; (6) the suturing of small wounds of the sinuses is also a very valuable means of hemostasis, but cannot be used except when a small wound is freely in view; (7) forceps pressure is a very ready means of controlling hemorrhage from one of these channels but has its own peculiar dangers and has really no distinct advantage over the other methods.

Significance of Retrodisplacements of the Uterus.—G. HEINRICIUS *(Arch. f. Gyn.,* B. 63, H. 3) in discussing the pathogenesis and clinical status of retrodisplacements of the uterus, especially retroversio-flexio uteri, comes to the following conclusions. In the first place he considers that the typical text-book symptom-complex of this condition does not belong to simple but to complicated cases of this condition, namely, to the associated lesions and not to the mechanical displacement itself. Such symptoms are due to the concomitant endometritis and metritis and other inflammatory conditions. True circulatory stasis by mechanical interference with the blood-current he denies, stating that after ligating the main venous outflow, as in ablation of the tubes and ovaries, no uterine turgescence occurs, and pointing out that in simple cases all signs of it are also absent. As to the cause of this backward position of the organ he states that most cases are entirely a matter of developmental anomaly. In about the same percentage the condition is found in virgins, nulliparæ and paræ. In a very few instances, indeed, is a previous anteversion or a previously normally placed uterus converted into a retrodisplacement by childbirth. The treatment of retrodisplacements consists first in diagnosticating and then in curing the associated lesions, namely, the endometritis, metritis, bladder affections, simple digestive constipation and other gastro-enteric functional disturbances, simple or pronounced neurasthenia, hysteria, etc. He denies that the backward bending of so small an organ can cause an obstructive constipation in the vast majority of the cases, because we have a very large pelvic strait in which often large tumors are found existent for many months without this symptom. The influence of the uterus upon the bladder is also combated for the same reason. Pain in the back is a symptom of which many women complain, not because their womb has any rational physiological relation with their loins, but because through some cause, often removable, they have strained their back muscles or are subject to the musculo-nervous symptoms of hysteria or neurasthenia. It is not reasonable to believe that an organ which has so little influence upon the life of the patient and without which so many women live well and long, can possibly be the origin of even a part of the curious manifestations ascribed to it. It is certainly a fact that when these associated symptoms are treated as indicative of entirely independent conditions, the patients get entirely well, although the womb remains in retroversioflexion. It is hence to be observed that no woman be told of such displacement before a continuous and rational treatment of these accompanying conditions be followed, in order to avoid the depression, fear and dread incident upon knowing that her womb is back—an organ movable and certainly in many positions each day.

Linen Lace in Surgery.—F. KUHN (*Centralbl. f. Chir.,* 1901, No. 24), in endeavoring to avoid the maceration incident upon the use of rub-

ber tissue and the frequent tearing away of the skin-grafts consequent upon applying some of the other usual means of protection, came upon the suggestion of adapting ordinary rather coarse-mesh linen lace, such as is used for window curtains, as the primary dressing. He makes it impermeable to water by saturating it with celluloid. After the grafts are in place this "lace guard" is laid evenly and smoothly over them and extended well beyond the limits of the granulating area upon the sound skin. Here it is carefully gummed down by the aid of collodion. Then the usual absorbent outer dressings are applied over this. The advantages of this simple device he has found to be as follows: (1) the meshes of the waterproof lace hold the grafts firmly in place; (2) the regular joints of the lace impose an even pressure at every point, which can be increased by heaping on several thicknesses; (3) the highly porous covering thus provided is a very certain outlet of the various wound secretions. He has also found that all the usual difficulties of the Thiersch method of skin-grafting have been overcome by this little technic.

Optic Atrophy in Diabetes.—H. F. HANSELL *(Jour. of Nerv. and Ment. Dis.,* July, 1901) reports a case of binocular hemianopsia and optic nerve atrophy associated with diabetes mellitus. Optic nerve disease is a rare complication of diabetes, recurring double iritis being the most common eye lesion. Amblyopia without ophthalmoscopic changes, often referred to by writers, is probably due in all cases to an intracranial lesion or is the earliest stage of the retrobulbar neuritis which leads to atrophy. Hemianopsia, optic nerve atrophy and amblyopia are probably but indication of the three stages of retrobulbar neuritis leading to atrophy.

THERAPEUTIC HINTS.

Corset for Movable Kidney.—The corset should be as long in front as can be worn, to elevate and support the redundant lower abdominal wall and form at the waist line a shelf on which the kidney may rest. Having thrown the corset about the waist, the patient lies on the bed, draws up the knees, places the head on a pillow to relax the abdomen, and pushes the kidney into place. She then hooks the corset from below upward, the redundant abdominal wall being drawn within it. She should never be permitted to maintain the upright position without her corset on. The best corsets are made to order but the "straight-front" corsets of the shops give very good results.—A. E. GALLANT in *American Journal of Obstetrics,* July, 1901.

Massage after Gonorrheal Epididymitis.—During the acute inflammation, advise rest, preferably in bed, with the scrotum supported, and the local application of leeches, ice, emollients, baths or mercurial and belladonna ointment. Bouisson applies chloroform, Paquelin, the continuous current, and Velpeau, paracentesis to relieve tension. Many men prefer compression by bandages, collodion, suspensory, etc. After the acute inflammation has subsided, the permeability of the vas deferens may continue impaired by exudates and the effect of the inflammation on its wall. Here massage has the mechanical effect of pushing the exudate onward, promotes its rapid absorption by increasing the lymphatic and venous circulation, and stimulates the nutrition of the tissues by increased flow of blood from the arteries.—CHARLES COLOMBO in *Revue de Thérapie Physique.*

Heroin.—The lethal dose of heroin is one hundred times greater than its therapeutic dose, whereas the fatal dose of codeine is but ten times the amount usually prescribed. Heroin does not affect the appetite nor disturb the stomach, nor in ordinary dose does it have much effect on the circulation, but, through an action on the respiratory center, breathing is slowed and the depth and strength increased. No narcotic effect is noted except after a large dose, but it causes dryness of the pharynx and slight irritation of the fauces. As an analgesic it is inferior to morphine. It can be recommended, however, as superior to morphine or codeine in conditions of dyspnea or irritative cough, though as yet it is not known whether the habit is likely to be formed or not.—B. D. GILLIES in the *Montreal Medical Journal,* June, 1901.

Spinal Anæsthesia.—It is not necessary to have the needle point in the spinal canal, as anesthesia is produced if the solution is injected about the region, yet the canal is easily found and the same amount of drug is more effective when placed in the canal. The needle is best inserted between the fourth and fifth lumbar vertebræ, the tip of the fourth spinous process being a guide. The patient should be in a sitting posture with spine well flexed. The cocaine may be weighed out in envelopes and sterilized dry, then made into solution with sterile water, or the solution may be sterilized in a water-bath. Analgesia begins in the soles of the feet and extends upward to the clavicle. Some patients become pale and nauseated in a few minutes and vomit, or there may be a tremor of the lower extremities, talkativeness, or occipito-cervical headache. Sometimes these symptoms are delayed for some hours. Bier found that the cocaine necessary varied in individuals from 1-3 cg. (gr. ⅙-½) and that in many cases cocaine poisoning supervened. He tried tropacocaine, eucaine and other drugs, but found none so efficient as cocaine. The most annoying symptom following its use is headache. This is somewhat relieved, however, by codeine, bromides, hyoscine hydrobromide, or nitroglycerin. The special indications for spinal anesthesia in surgery are general peritonitis, distention of stomach and intestines, lung disease, disease of the kidneys, and advanced disease of the heart. It is also used in sciatica and in obstetrics.—ANGUS MCLEAN in the *Philadelphia Medical Journal,* July 6, 1901.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SMITH ELY JELLIFFE, A.M., M.D., Ph.D., Editor,
No. 111 FIFTH AVENUE, NEW YORK.

SATURDAY, JULY 27, 1901.

NEW YORK'S HEALTH AND STREET CLEANING DEPARTMENT.

NEW YORK is a very dirty city at present, disgustingly dirty in fact. A Turkish town could hardly show more garbage, more dead animals or more general filth than some of the crowded streets of this much governed town. The day of Waring is like a white dream; but under Waring the Street Cleaning Department dreamed no dream; it worked. Now it leans back and fans itself and shrugs its shoulders. A great excuse pervades New York. It lies along its thoroughfares, it monopolizes its corners. It is the tunnel. While the avenues are turned into earthworks and the centers of traffic are blockaded, the Street Cleaning Department feels that it would be a waste of the people's good money to be continually cleaning up a street that needs just as much attention the next day, and so dirt and mud and dust and waste paper accumulate around the unsightly gaps in the streets and in the remoter corners of the city.

Added to the tunnel excuse is the hot wave excuse. The Street Cleaning Department is adjusted to an average daily allotment of dead horses, and starved cats in summer, but when the number jumps up ten times, what else can it do, but jog along and bury them in the order of their decease? The same sort of excuse might have served Colonel Waring when a young blizzard passed over the city and dropped uncounted tons of snow into the streets of New York for the citizens to plough into mire and slush. But Col. Waring was a man of action and not of excuses. He had obtained from reliable sources the information that New York was subject to snow storms that resulted in wet trousers and skirts for the pedestrian millions of the city, and that grip, pneumonia and sudden death were the inevitable result of jogging on and letting Nature take her course with the snow, as she is doing at present with the bodies of dead beasts. He was prepared for the emergency, and the people of New York went to their business as dry of foot as the Israelites crossing the Jordan.

Now the present Street Cleaning Department could have forecast how the combination of a tunnel and a hot wave would affect the city's appearance, and, instead of getting Monday's work done by Saturday night and keeping the Sabbath in a pious and discouraged frame of mind, it might have had an emergency force ready to do each day's work promptly, to do it in the cool of the day, to do it in the dead of night, as long as it was done.

The dust that is blowing and sifting through the city is a menace to health every hour of the day. The city needs constant sprinkling. The fleas and pests of uncleanliness that are beginning to swarm are indicative of plentiful breeding-places that need scrubbing out. The diseases that come from decaying matter are too many to mention. Were we subjects of the Sultan we might shrug our shoulders and say "As Allah wills," but being responsible and intelligent citizens, as well as physicians, we demand better returns for our investments.

ETIOLOGY AND TREATMENT OF "CHRISTIAN SCIENCE."

IT is still a disputed point whether the primary cause of "Christian Science" was a mental instability or a clever business venture on the part of its founder. Certain it is that she has displayed great cleverness in her personal proof that in Christian Science there is no such thing as poverty. Like an echo of Mrs. Eddy's voice comes from Chicago the message of Dowie, "the prophet," alias Elijah, alias John the Baptist:

" Listen to the first message of the prophet. You must pay your tithes and offerings."

The contagiousness of the affection may be attributed largely to a desire for novelty. This is well developed in those in whom ideas of a religious character are absolute strangers, or have never been thoroughly awakened and so appeal as completely new, arousing excitement and enthusiasm as does a " revival." The belief is optimistic—no sickness, no poverty—and so attracts pleasure-lovers. These four elements—hysterical excitement, instinctive religious cravings, love of mystery and of pleasure—are the most potent factors in supporting new movements. That which is founded upon the first of these is usually short-lived, and wisely the pseudo-scientists have subordinated this element to the others. The introduction of a garbled religious element is one of the most dangerous features of the so-called science, and its chief aid is the factor of mystery furnished by the meaningless transpositions and combinations of words in its ritual, and by the adoption of the technic of the quack. The gullibility of the public concerning medical matters is most natural because of their ignorance of these subjects, and those who will accept the ministrations of the advertising " doctors " and " professors " are certain to be reached by the additional attraction of the religious element, particularly when this inculcates the doctrine that there is no poverty, no pain, no sin.

Christian Science is dangerous because it appeals to those who, unable to follow an argument logically, are lead by meaningless but to them high sounding words. Reaction is sure to follow, as in other movements resting upon unstable bases.

How is this reaction to be hastened and the symptoms of the disease limited? Direct legislation against the so-called Christian Scientists, if it were possible, would merely lend the aid which persecution always does, and would enable them to pose as martyrs, while evasion of any law is possible. Restriction of individual liberty will not be tolerated in this country. It would be difficult to convince many that a man has not the right to his own beliefs, and just this point makes the insertion of the religious element most dangerous. While public opinion condemns the action of the would-be suicide and no difficulty is experienced in securing legislation against one who attempts to take his own life, it is another matter to secure such universal approval of adverse legislation if the same attempt be made under guise of a religious belief. The so-called Christian Scientist does not openly claim the right of suicide or murder, but does so indirectly by his refusal to accept medical aid, and supports his action by the plea of religious conviction—an inviolable matter. Against this defense direct legislation is difficult and of questionable value. It has been shown, too, that forbidding the practice of Christian Science for pecuniary reward would be inefficacious, as this law could be circumvented by the acceptance of gifts from the patient before or after rendering service claimed to be religious in character.

The point which it appears can be controlled by law is the refusal to permit medical care of others, which bears to their own refusal of such assistance the same relation which manslaughter does to suicide. The enforcement of laws making such wilful disregard of the lives of others punishable as manslaughter seems possible and should be effectual. A man is entitled to free enjoyment of his opinions only so long as they do not interfere with the rights of others. No one has the right to sacrifice the life of another for pecuniary gain or in connection with a delusion. If an attempt were made to escape imprisonment for manslaughter under such a law, on the plea that the defendant believed it right, the only logical conclusion would be that he was suffering from a delusion dangerous to others as well as himself and required confinement in an asylum for the insane. Against such offenders the sanitary code cannot be too rigidly enforced as the rights of others are concerned, particularly in relation to contagious diseases. The recent decision of Judge Tuthill of Chicago that children of parents who refuse them medical aid when ill should be committed to the care of medical institutions is a step in the right direction. To this extent legislation may go, on the ground of defending the rights of the public, without entering too deeply upon the question whether a so-called religion which justifies manslaughter, suicide, and also immorality by claiming that there is no sin, can lawfully be interfered with. To this limitation of results it appears that direct treatment of the acute attack of the delusion must be confined.

Prophylaxis is all important. Reaction against the new fad can most surely be brought about by preparing the coming generation for logical consideration of the delusions which will be

presented to them. General education is of value in enabling the detection of the fallacies with which the doctrines are so filled, but which are carefully hidden from the mind untrained for analytical thought by the barriers of meaningless phrases. The surest means of attack from a medical standpoint lies not in direct opposition by members of the profession, as this is sure to be ascribed by the followers of Mrs. Eddy and by many others to fear of competition.

Education is the greatest foe of superstition and ignorance, and this applies as fully to the treatment of Christian Science as to the overthrow of the power of the quack. The hold upon the community which the delusion possesses is obviously due largely to lack of knowledge of bodily laws. No one who possesses any connected understanding of anatomy and physiology can fail to see that matter does exist and is influenced by matter as well as by mind. To such a person the claim that a rubber plant can be treated effectually by Christian Science, or that all bodily ills can be cured by mental influence, seems as false as that perpetual motion can be secured by appeal to that power. Perpetual motion! What a financial possibility for Mrs. Eddy!

TRICHOTOXICON AND BALDNESS.

IT IS probable that ever since time began the premature loss of the hair of the head has been regarded as a personal calamity and the unfortunate being afflicted with calvities has been subjected to the unfeeling scoffs of his more hirsute peers. It is a far cry from the jeers of the *gamins* of Jericho, which so infuriated the baldheaded prophet Elisha that he turned upon them and cursed them, whereupon we are told, "There came forth two she-bears from the wood and tare forty and two children of them," to the stigma that in modern days attaches to the first row of orchestra chairs, yet through the ages the finger of derision has been steadily pointed at the luckless baldhead and it has ever been a shining mark for the witticisms of the unregenerate. Therefore it is not surprising that the nature of this deplorable state has formed the subject of much learned ratiocination and many and various are the hypotheses that have been formulated to account for its origin. Some of these seem plausible enough, yet here, as often in other matters, the problem of sex has proved the rock upon which many a well-trimmed theory has split, for but few navigators in this particular stream have been able to do more than be thankful that woman, at least, is exempt and usually preserves her crowning glory to the very end.

But the ingenuity of the theorists has not been wholly baffled and many have found in the differences in head-gear affected by the sexes an explanation which comforts and satisfies their questing spirits, while other daring searchers after truth have not scrupled to lay bare even the mysteries of the bedchamber and assert that woman's method of emerging from her *robe de nuit,* since it spares her the cephalic friction that attends man's more headlong maneuver, is the chief bulwark and defense of this, her most cherished beauty.

But all these vagaries are destined to speedy oblivion, for a new prophet has arisen and, like young Lochinvar, he comes out of the West. Dr. Delos Parker of Detroit is his name and the *Medical Record* of July 13th is his mouthpiece. From his utterances it appears that an explanation of woman's capillose superiority resting upon true sexual differences has at last been found. Alopecia is a form of auto-intoxication depending upon the absorption of trichotoxicon, a substance formed under the influence of warmth and moisture in the unventilated portions of the lung. Man being an abdominal breather, the apices of his lungs remain relatively quiescent and furnish admirable laboratories for the elaboration of this poison, while woman, through the costal respiration forced upon her by her corset, saves her hair at the expenses of her liver and other abdominal viscera.

In the interest of the dress-reform movement we trust that this information will not become generally disseminated, yet it is pathetic to think how much human suffering would have been averted had the crinicultural value of the corset only been earlier recognized and what multitudes of glabrous calvaria might have been luxuriantly clothed had their owners only learned in time to breathe properly by encasing their manly forms in stays.

TUBERCULOSIS IN ITS HUMAN AND BOVINE RELATIONS.

THE recent announcement of Dr. Robert Koch of Berlin before the British Congress for Tuberculosis that bovine tuberculosis is not communicable to the human species will be received with the deepest interest, but not without much surprise and considerable skepticism on both sides of the Atlantic.

The scientific data and details upon which Professor Koch bases his startling conclusion are not now at hand, but it may not be amiss at this point to recall some observations which may prove difficult of explanation should his conclusion be confirmed by others. For our own part we do not feel disposed to regard, without certain limitations, such a belief either probable in truth or consistent with experience. However, we reserve a fuller appreciation of the distinguished scientist's results and criticism of his arguments for a subsequent time. Of the statement one might well say:

"Till at last the waves so high do rise,
"As seems to bid defiance to the skies."

The belief that bovine tubercle bacillus is incapable of inducing tuberculosis in man is, of course, by no means new. For years there have been advocates of this side of the question; and it is only about two years ago that an article embodying the same conclusion was written by Dr. Edward Moore of Albany, N. Y., who, taking this view of the matter, had made especial use of the results obtained by Dr. Theobold Smith in his comparative study of tubercle bacilli of bovine and human derivation. Although these results suggest certain morphological, cultural and experimental differences they by no means establish any inability on the part of the bovine tubercle bacillus to incite tuberculosis in human beings.

As a matter of fact there is an abundance of clinical evidence which indicates this capacity. Thus Tscheving of Copenhagen in 1888 reported a case in point. The sufferer was a veterinary surgeon who wounded his finger while making an autopsy on a tuberculous cow. Local tuberculosis in the wounded part developed in a short time. Lefévre (*Sur la tuberclose par inoculations cutanée chez l'homme,* Paris, 1888) collected other equally striking examples which would be very difficult of explanation if our present view is incorrect.

ECHOES AND NEWS.

NEW YORK.

Brooklyn Death-Rate about Normal.—The death-rate for Brooklyn for the week ending July 20, 1901, was 485, about the normal rate for this time of the year. Seven of these deaths were due to the heat. The mortality among children was 144.

Green Men for the Work.—On account of Civil-Service complications the Brooklyn Health Department has been obliged to dispense with the services of the physicians recently appointed on the "summer corps." These men were assigned to do duty as vaccinators and the Civil-Service Commission has ruled that all such must be appointed from an appropriate eligible list.

St. Mary's Hospital Appointments.—Drs. J. Richard Kevin and E. Arthur Parker have been appointed surgeons, and Drs. Thomas F. Mylod, John Lee, Robert Morrison and Joseph Murphy, assistant surgeons.

A Coroner in Trouble.—Affidavits charging Coroner Geo. W. Delap of Brooklyn with unlawfully extorting bribes and conniving at false verdicts at inquests have been placed in the hands of District Attorney Clarke for investigation. The principal charge against Dr. Delap is made by Mrs. Kate Leutz, a widow, who accuses him of extorting $100 from her on a threat that she could not collect the insurance on her husband's life unless she paid $75 to him and $25 to Coroner's Physician Henderson, since deceased. Dr. Delap denies the charges *in toto.*

To Report on Central Tunnel.—As a result of complaints voiced through the *Evening Post,* Commissioner Sexton of the Health Department, this afternoon, sent two inspectors to make a report on the conditions prevailing in the New York Central Railroad tunnel. Commissioner Sexton has laid the matter before the counsel for the Department, and doubts whether anything can be done, even if the inspectors say that the tunnel is detrimental to public health.

To Fight the Mosquito.—The Health Officer of the Port, Dr. Alvah Doty, has decided to take hold of the mosquito question on Staten Island, and attempt the extermination of these pests. A section of the island adjacent to the Quarantine Station has been selected for the test. Dr. Doty said of his plans last week as follows: "We have been at work for the past year in our laboratory on the mosquito larvæ, in order to determine bacteriologically what can be done. The first thing is to determine if the insect produces malaria; the second is to answer the question, if so, can malaria be prevented by the extermination of the mosquito and its larvæ? The test I have determined to make will be applied to a section of Staten Island adjoining our station, and opposite the quarantine islands, in extent about three miles by one and one-half miles. The boundaries of this section are New Dorp Lane, Richmond Road, Vanderbilt Avenue, and New York Bay. All the swamps, ponds, marshes, and wet places will be inspected by men from our laboratory, to determine just where the possible breeding-places are located. The mosquito and its larvæ will be taken in such places, and will be examined to determine the presence of malaria. Local physicians will be asked to co-

operate by reporting all cases of malaria. All intelligent cooperation of citizens also will be requested. In the treatment of breeding-places petroleum will be an important factor. This test is in line with our quarantine work, as the quarantine hospital for yellow fever is located adjacent to the section selected for the test." Some Staten Islanders, annoyed at mosquitoes, have found an extract made from citronella a good means of personal defence. The extract is used like fly oil; that is, rubbed on the face and hands.

Health Department Appointments.—The Municipal Civil-Service Commission recently announced several appointments to positions in the city departments. Among them were the following: Theodore Walser, Assistant Sanitary Superintendent, Department of Health in the Borough of Richmond, $3,000. Arthur F. Simonson, Lay Sanitary Inspector, Department of Health, Manhattan, $1,200. Oswald B. Franz, Lay Sanitary Inspector, Department of Health, Manhattan, $1,200.

PHILADELPHIA.

City Hospital to Be Improved.—The Philadelphia Hospital is to be improved at once, whether the Almshouse and Insane Departments are removed or not. The Petty Island site for the latter has not been decided upon, the prevalence of malaria being an important argument against its adoption. The improvements to be added are to cost $80,000, being distributed as follows: Children's hospital, $35,000; hospital for contagious skin diseases, $35,000; maternity house, $10,000.

University of Pennsylvania.—The chair of assistant clinical professor of genito-urinary diseases has been filled by the appointment of Dr. Thomas R. Neilson.

Outings for the Indigent of the City.—Movements in aid of the various fresh-air enterprises are unusually popular this summer. The Children's Sanitarium at Redbank is caring for its full capacity daily. The several seaside homes and hospitals maintained at Atlantic City by individuals and corporations of this city are filled and have hundreds on the waiting list. Several of the daily papers have instituted homes for children, started free ice funds, etc. These measures undoubtedly saved numbers of lives during the recent heated spell.

Quarantine Physician a Victim.—Dr. J. R. Caldwell of Chester, late quarantine physician at Marcus Hook, died July 21st. Dr. Caldwell was taken ill some time ago as the result of fumigating a ship and was in a critical condition during the past month. He served with distinction during the Civil War and was at one time a leading politician.

Hospital Appropriations Reduced by the Governor.—Mention was made in this column some time since of the dissatisfaction caused by certain appropriations by the Legislature. The changes made by the Governor before signing the bills have shown that a portion of the storm of protests were not called for, but they have caused additional disappointments. Many of the reductions affect the smallest institutions of the State, but the larger ones have been greatly reduced. The appropriation bills as signed include the following hospitals: University of Pennsylvania, $10,000; Jefferson, $50,000; Medico-Chirurgical, $40,000; Hahnemann, $5,000; Samaritan, $5,000; German, $38,000. The State Homeopathic Hospital for the Insane gets $250,000. The Free Hospital for Poor Consumptives receives $60,000.

CHICAGO.

The State Board of Charities.—This body has issued its quarterly bulletin for the three months ending June 30, 1901. The average number of inmates of the fourteen charitable institutions of Illinois during the quarter was 9,000. The net average cost *per capita* was $38.78, and the gross cost $43.91. The total cost of all the institutions was $432,743.66, and their total income $479,407.29. There is a total surplus of $103,666.53 in charity funds, and only $36,669.29 of debts.

Appointment of Dr. Porter.—Dr. Ralph S. Porter has been appointed surgeon of volunteers with the rank of major. He graduated from Rush Medical College in 1897. At the outbreak of the Spanish-American War he enlisted with the Second Illinois as assistant surgeon with the rank of lieutenant, and served with that regiment until May, 1899, when he returned to Chicago. On July 1st following he was appointed assistant surgeon to the Thirty-first Volunteers and assigned to duty in the Philippines. Major Porter is said to be the youngest medical officer in the United States Army to-day with the rank of surgeon major.

Dr. Senn's Trip around the World.—Under date of July 14th, Dr. Senn writes his first of a series of articles for the *Chicago Tribune*. In it he deals with the importance and necessity of professional men, particularly physicians, taking rest and recreation. The physician who has the interests and welfare of his profession at heart chooses a vacation which will secure rest for his weary brain and at the same time give him an opportunity to increase his knowledge of the various diseases and their treatment. A leisurely journey from one medical center to another will accomplish this, especially if combined with an ocean voyage. Such an itinerary gives him an opportunity to visit different countries, observe the habits and customs of the people, familiarize himself with the advantages and methods of education of different institutions, cultivate the acquaintance of men eminent in his profession as authors, teachers and practitioners, and observe

their methods of treatment. All this requires no special mental effort, and yet fills the storehouse of practical knowledge to a wonderful extent.

Physical Examination of Female School Teachers.—The physical examination of 300 candidates for places as school teachers was recently concluded. The average of the candidates taking the test was exceptionally high. Only a few were rejected, although the requirements were severe. The examinations were much the same as those of applicants for life insurance, with added optical and aural tests and examinations for evidence of disease and physical deformities. The result of the examination proves the truth of the conclusion reached in the work with school children, *i. e.*, that there is a distinct relationship between physical condition and intellectual capacity, the latter varying directly as the former. In the tests for vital capacity the great breathing capacities of the candidates who had taken gymnasium work at the school and had been prominent in athletic sports was in great contrast with those who took little physical exercise, suggesting that vital capacity increases and decreases with the amount of activity.

Finds Many Deformities.—Among the hundreds of cases of freak hands or feet which have been discovered and recorded by Professor Frederick Starr, of the Anthropology Department of the University of Chicago, are fifty minute descriptions of Chicagoans who have either too many or too few fingers and toes. Professor Starr has made another appeal to the members of his class for the names and addresses of people with superfluous members. He announced that it was his purpose to get full data upon 500 cases and then he would begin to formulate a new theory. Already he has records of 350 cases, some of the subjects having six, seven, and even nine fingers or toes on one extremity. Among the observations which he has already made is one to the effect that such deformities are more common in large than in small families.

Bogus Philanthropist.—Warden Healy of the Cook County Hospital recently discovered that a woman has been masquerading as a benevolent worker, when her real business has been to solicit patronage for a certain lawyer who makes personal damage suits a specialty. Although her ostensible mission was to bring tracts, flowers and sympathetic messages to the suffering, she was overheard to urge the objects of her attention to retain Attorney —— as their legal representative, and the Warden, who is making a heroic effort to clear the hospital of all claim agents, gave orders that hereafter bogus philanthropists be refused admittance to the wards.

Establishment of Sanitarium at Janesville, Wis.—Several of our leading physicians recently visited Janesville to consider the establishing of a large sanitarium at that point.

GENERAL.

Viscogen, a New Milk Adulterant.—Housekeepers and pure-food commissioners have a new foe to fight. It is viscogen as a milk adulterant. It has been found by inspectors of the Dairy Department in Minnesota, and, so far as known, its use is yet confined to that State. When its properties become generally known, however, it may confidently be looked for elsewhere. It is a syrup composed of sugar, lime, and water, about the color of water, and is used chiefly to make the milk appear richer than it really is. When viscogen is placed in milk or cream the lactic acid turns the lime in the fluid into a white, thick substance, which, assimilating with the milk, gives it an appearance and taste of great richness. It is possible through its use to palm off upon customers milk and cream which are far below standard.

Tuberculosis Among the Indians of Southeast Alaska.—Dr. Fox, of the Marine Hospital Service, reports on this as follows: "While in Alaska I learned that tuberculosis existed among the natives to quite an extent. While my observations on the subject were very superficial, I had a number of cases pointed out to me by the physicians as being of a tuberculous nature, obtained histories of hemoptysis, and saw many cases with symptoms of cough and a very suspicious-looking, profuse expectoration. Not only is the pulmonary form common, but one sees many cases of tuberculosis affecting the cervical glands and the bones and joints. The good effect of plenty of fresh air, which the Indians obtain while roaming around in the warmer weather, is rendered valueless by the evil effect of filthy surroundings while housed for the winter. Their houses are very dirty; in fact, I suppose they are not scrubbed out from one year's end to the other. Several families are crowded into one house, and when we consider the fact that many of them expectorate on the floor, the sputum, no doubt, often swarming with tubercle bacilli, it is no wonder that tuberculosis is so prevalent."

Public Tuberculosis Sanitarium for England.—At Tuesday's session of the Tuberculosis Congress, the Duke of Cambridge announced that a gift of £120,000 ($600,000) would be forthcoming for the purpose of establishing a public tuberculosis sanitarium as soon as the recommendations of the Congress concerning its establishment had been formulated.

Connecticut Consumptives' Hospital Begun.—Work upon the Consumptives' Hospital that is to be erected on Newington Mountain, a high suburban section of Hartford, was begun last week. The State has appropriated $25,000 for the enterprise, and an amount nearly as large has been contributed by private subscriptions. The undertaking represents the

first effort made in Connecticut for the segregation of the victims of pulmonary tuberculosis and their isolation treatment in an institution. The hospital building will be 276 feet long, and the central section will be two stories high. One wing will be for men and the other for women. The medical profession of the State is taking a keen interest in the project.

Opening of the Tuberculosis Congress.—Some twenty-five hundred British and foreign delegates were present at the opening of the International Congress of Tuberculosis, which His Royal Highness the Duke of Cambridge opened Monday, July 22d, in behalf of the King. It may be doubted if the roof of St. James' Hall ever covered a more distinguished assembly. His Royal Highness was chairman, immediately supported on the right and left of the platform by the American and French Ambassadors, the Ministers of Portugal, Denmark, the Netherlands and Greece; the Marquis of Lansdowne, Earl Cadogan, Lord Strathcom, the Lord Mayor, Lord Lister, Lord Derby, Sir James Blyth, Professor Clifford Allbutt and Sir James Crichton-Browne, while in the serried ranks which filled the tiers of the great platform were the Duke of Northumberland, the Marquis of Bath, Earl Spencer, Colonel Fitzgeorge and Professor Koch. Nearly three hundred other leading representatives of British, foreign, American and colonial states and associations were present. Mr. Malcolm Morris, Honorary Secretary, read the report of the Committee, which laid emphasis on the part taken by His Majesty in promoting the Congress, and the assistance rendered by the Marquis of Lansdowne and Mr. Chamberlain in forwarding the invitations to foreign countries and the colonies. The Duke of Cambridge said: "It becomes my duty to open the Congress at the request of His Majesty the King who had intended personally to have taken the chair, which under the present circumstances he cannot do."

Shortly before the close of the afternoon's proceedings the following telegraphic message was received from King Edward:

"I have just received your telegram, and thank you for having kindly consented to open the Congress in my name. I am glad to hear that the ceremony passed off so well. I pray you heartily to thank for me the eminent men belonging to almost every nation who have assembled to-day under your presidency, and to express to them my earnest hope that the valuable information which they will give to the world as the result of the deliberations of the British Congress on Tuberculosis will further assist in mitigating that dire disease which has baffled the most distinguished physicians so long. "EDWARD REX."

Lord Lansdowne, in behalf of His Majesty's Government, tendered a cordial welcome to the foreign delegates, saying: "This nation has lately been passing through all the anxieties and sorrows of a prolonged war, which has carried to many of their homes desolation and calamity. But no war that was ever waged brought with it anything like the burdens of misfortune which tuberculosis from time immemorial has carried to every land. Happily, they are no longer regarded as an inevitable scourge."

Lord Lister spoke for the medical profession of the islands. Thanks, he said, to the illustrious man who would address them to-morrow, Dr. Koch, they now knew the enemy they had to fight. They also knew from Dr. Pasteur that this enemy, the microbe of tuberculosis, like all others, was incapable of originating *de novo*, but must in all cases be derived from a similar organism. Here there arose a hope, a splendid prospect of prevention. But they did not look to prevention only; they might also seek to cure consumption. In this respect, matters recently had become much more hopeful. They were learning more every day of the powers of the animal organism to resist the invasion of the bacillus. The physician might learn something of the surgeon in this respect. They could sometimes sweep away the bacillus and restore the organism affected to its prestine health. He hoped the deliberations of the Congress would be fraught with good, but the general public must help the physician and surgeon. He trusted that the assembly of scientific men from all parts of the world would indicate the means by which it would be able eventually to stamp out this great scourge of the human race.

Obituary.—Dr. Adolph W. Dunbar, a well-known young physician of Brooklyn, died on Saturday of typhoid fever at his home, 22 Seventh Avenue, in his twenty-eighth year. He was a graduate of the Polytechnic College in Brooklyn, Princeton College and Bellevue Hospital. He was a member of the Crescent Athletic Club, the Princeton Club and the Long Island Medical Association.

Dr. George A. Blanchard, Assistant Surgeon of the Thirteenth Regiment, died July 19th of typhoid fever. He served as surgeon throughout the Spanish-American War.

Dr. L. Wolff, widely known among the medical men of Philadelphia as a throat and nose specialist, died suddenly July 21st, of Bright's disease. Dr. Wolff was formerly on the staff of the German Hospital, but lately had given his entire attention to the practice of his specialty.

Plague in New York Harbor.—A case of plague has just been discovered in an entering vessel in New York Harbor.

State Laboratory Opened.—The State Laboratory for the production of anti-typhoid, antitetanus and other remedial sera has just been opened.

CORRESPONDENCE.

VALVULAR DISEASE AND PULMONARY TUBERCULOSIS.

To the Editor of the MEDICAL NEWS:

DEAR SIR: I should be excessively obliged to the subscribers of your valuable journal for answers to the following queries:

I. In what percentage of the cases of chronic valvular disease affecting the mitral and aortic segments has pulmonary tuberculosis developed as a secondary event?

II. If notes have been kept, kindly give the total number of cases, both of valvular disease and pulmonary tuberculosis, as well as the percentage.

III. If no records have been kept, kindly state opinion as to the frequency of the occurrence of pulmonary tuberculosis secondary to chronic valvular disease at the orifices mentioned above.

IV. What is the effect of valvular disease, mitral and aortic, upon the course of chronic pulmonary tuberculosis?

V. Have lesions of the pulmonary artery valves seemed to predispose to pulmonary tuberculosis? (Statistics on this head are also desirable.)

VI. If chronic valvulitis affecting the mitral and aortic cusps exercises a preventive effect, what is the explanation?

VII. If disease of the pulmonary valves (I refer especially to stenosis) predisposes to phthisis, how is the effect accounted for?

J. M. ANDERS.

1605 Walnut Street, Philadelphia, July 17, 1901.

OUR LONDON LETTER.

(From Our Special Correspondent.)

LONDON, July 12, 1901.

A DULL TIME—THE COMING ANNUAL MEETING OF THE BRITISH MEDICAL ASSOCIATION—THE MYSTERY OF BRITISH MEDICAL TITLES—"DRS." AND "MRS."—GRADUATES AND LICENTIATES—"BRUSSEL SPROUTS"—THE LAMBETH DEGREE.

IT has been said by some philosopher that the nation is happy which has no history. If this be so, the medical profession in these realms must be happy at present, for there is absolutely nothing to record in the way of incident. The General Medical Council has ceased to trouble and societies are at rest. The promoters of the Tuberculosis Congress are busy with their preparations, and the wirepullers of the British Medical Association are stringing their puppets ready for the show. At the latter meeting the question of reorganization will be discussed, and as there is a good deal of feeling about the matter in various quarters, there may be what our Parliamentary reporters call a "scene"—indeed, several "scenes"—"in the House." As I have already told you, the great body of the Association cares nothing about reform and the whole movement is the work of a few malcontents. But as a handful of active men who know their own minds can carry anything against an army of indifferent persons, it is probable that some sweeping measures of "reform" will be carried. What the issue of these may prove to be, it is impossible to foresee; but it is quite possible that it may be to reform the venerable Association itself out of existence. It is pretty certain that large numbers of members will resign if they are called upon to pay an increased subscription and compelled to belong to a Branch instead of adhering with convenient independence to the parent stem. But my business as your correspondent is, I take it, to speak of the present, not the future.

In default of anything better, it may be useful, if not very interesting, if I try to elucidate to your readers the mysteries of our medical titles. I have often had occasion to note that they puzzle our American visitors; and, it must be admitted they are very perplexing to the uninitiated. The subject is suggested to me by the fact that at present the question of titles is being debated in the medical journals, as it has been from time to time for the last thirty years. Within the memory of many people now living the profession in England was divided into physicians, surgeons and apothecaries. The physicians were "Doctors of Physic," as the degree is still called at the Universities of Oxford and Cambridge, and the possession of that academic dignity implied a residence of some years at College and a degree in Arts, with a corresponding amount of culture and all the other consequences of a youth passed in a good social environment. To attain to the rank of physician was the privilege of the few, for graduates of Edinburgh and the other Scottish universities were not held to be of the same standing as the men of the ancient English universities. Indeed, it was not easy for a graduate of any other university than Oxford or Cambridge to be admitted to the fellowship of the London College of Physicians. The foundation of the University of London in the early thirties made "physic" more democratic and realized Napoleon's program of *la carrière ouverte au talents.* The poorest lad who had brains carried the M.D. diploma in his pocket. The late Sir William Jenner used to say that if it had not been for the establishment of the University of London he could never have passed through the sacred portals of the College of Physicians. As a matter of fact, he began his professional life in a very lowly sphere of practice. The shop is still shown where the future medical counselor of Queen Victoria made up bottles of medicine and sold smalltooth combs. At that time the general practitioner or "apothecary" was not a graduate. He had passed the "College" and "Hall," like Bob Sawyer, and called himself "surgeon and accoucheur." Half a century earlier he would have been styled a "man-midwife" like Dr. Slop. The title of "surgeon" was a curious misnomer, for surgery was the branch of the art that he meddled with least. To his patients he was the "apothecary," and dames

of high degree spoke of "using the 'potecary.'" In George Eliot's "Middlemarch" a lady complains that Lydgate is a gentleman by birth and, therefore, she finds a certain awkwardness in "using" him; and English ladies in real life not so many years ago have been heard to say that they did not care to have as medical adviser a man whom they might meet at dinner. I suppose in certain cases the feeling would be something like that which a devout Catholic might feel in dining with his confessor. The apothecaries of course, always went by the style and title of "Mr." because they had no right to that of "Dr." Hospital surgeons, too, were plain "Mr." because they were generally not graduates of a University, but members or fellows of the College of Surgeons. So thoroughly established, indeed, is the custom that even nowadays when there are many Doctors of Medicine holding appointments as surgeons to hospitals, etiquette forbids them to use their title of Dr.

Nowadays there has been a great leveling up in point of education, and the rank and file are no longer content to be even "a little lower than the angels." Besides, there are greater facilities for getting a university degree, and one degree is pretty much as good as another, except that the doctorate of the older universities still carries with it a certain prestige, and that of London is held to represent the greatest amount of book work. But there is still a large proportion of the profession in England who, from being in too great a hurry to get into practice, or from not realizing the disadvantages at which the want of a degree would place them, were satisfied with a license. This can be got from the College of Physicians and Surgeons in London, Edinburgh and Dublin, from the Faculty of Physicians and Surgeons of Glasgow, and from the Society of Apothecaries, London. Holders of these licenses are strictly not titular "Drs." and, though courtesy may often concede the title, discourtesy can always refuse it. The Universities nearly all give the degree of "Bachelor" as well as "Doctor," of Medicine; and many are content to remain "M.B." without going on to the higher degree. Bachelors of Medicine have no right to claim the title of "Dr.," though they generally assume it; indeed, the Universities of Oxford and Cambridge expressly sanction the assumption everywhere except within the precincts of the University.

In Scotland where a university education has long, without the help of Mr. Carnegie, been accessible to every one who cared to work for it, all practitioners, with very rare exceptions, are graduates. But in England the majority are licentiates and the same in a less degree may be said of Ireland. But it is becoming more and and more the rule to take a degree, and the licentiates find themselves more and more handicapped in the race of professional life by the want of one. Hence, every now and then a wail goes up from them, and they call on the Colleges, on the General Medical Council, on the British Medical Association, and on the Government to do something for them. Some of them go abroad and pass a hurried examination, through an interpreter, and come home with all the blushing honor of a Belgian degree full upon them. This degree which does not give the right to practise in the country where it is issued is not thought much of, and the holders of it are playfully termed "Brussel sprouts." A few manage to get a degree from the University of Durham which humanely offers to examine practitioners of fifteen years' standing. But most of the licentiates would like to get a degree without the ceremony of an examination.

There is no doubt that it is a hardship for men in middle life to find themselves at a disadvantage with younger competitors who have had greater facilities for getting a degree. Twenty-five years ago the degrees of the older Universities were still only for the few; now Cambridge is the largest medical school in England. In those days students who wished to profit by the immense clinical material of the London Hospitals had practically only the University of London open to them; and the way to the degrees of that institution was long and also rough and beset with pitfalls. But it is not easy to see what can be done for the numerous licentiates who wish to exchange their plain "Mr." for the more learned prefix "Dr.," as only a university can now grant a degree. I say "now" because till the passage of the Medical Act in 1859 the Archbishop of Canterbury had the power of conferring the degree of "Dr." This was a survival of the medical system which made physicians dependent for the right to practise on the ecclesiastical authorities; and was very rightly swept away as an anachronism and an abuse. It is but fair to say, however, that the privilege was at least in modern times very seldom exercised by the Archbishop. The last holder of a "Lambeth degree" died some years ago.

If by a temporary stretch of grace the privilege —or something analogous thereto, to be exercised, say, by the Privy Council—could be revived, so that a degree might be placed within the reach of every deserving practitioner of a certain age too busy to be able to get it otherwise, a satisfactory solution of a problem of practical importance to a good many worthy men might be arrived at.

THE DEVELOPMENT OF THE PARASITES OF BIRD'S BLOOD IN MOSQUITOES WHICH RESEMBLE THE MALARIAL ORGANISMS.

HERR NOCHT, at the Biological Section of the Medical Society of Hamburg, April 23, 1901, read a contribution on the development of certain parasites, resembling the malarial organisms, common in the blood of birds in mosquitoes. The author at first rehearsed the development of the

human malarial parasites in their intermediary host, the mosquito, and showed demonstration specimens. This cycle of development had been fully and diligently worked out in its every detail by the Italian investigators after the way had been primarily pointed out by Ross, MacCallum and Koch. The author himself had not yet fully succeeded in observing this cycle in its entirety in the short time since the establishment of the Hamburger Tropenhygienisches Institute. Although a very large number of malarial patients present themselves at the hospital, there are few who harbor the right stage of the parasites for such inoculation of mosquitoes. These types—the crescents of the tropical malaria and the spheroids of the tertian and quartan—are not found unless the patient has undergone several repeated attacks of the disease. Such victims are rarely found to-day among the sailors in a port like Hamburg, because in the short voyages of the modern steamship and brief port-calls only fresh infections occur. Further, the right kind of mosquito does not exist in Hamburg and its environment, namely the *Anopheles*. It also happens that in spite of all possible haste fresh importations of the *Anopheles* from outside arrive too late, because it is not right to keep the sufferers too long without quinine therapeusis. His ordinary source for the supply of the *Anopheles* is the marsh-country of the North Sea, where they are more abundant than the ordinary kind of mosquito, the *Culex*. Therefore in the German marshes there are the necessary kinds of mosquitoes for the intermediary development of the malarial organisms, but no one seems to think it necessary to sleep under mosquito-netting or to take other protection against the disease. The reason for this, as Koch has already suggested, is that by proper treatment the recent infections are not allowed to go on to chronic malarial poisoning, and therefore the disease is almost extinct among the people. Such patients at once seek medical aid, are quickly cured and therefore do not go about among the marsh-dwellers as the source from which the *Anopheles* may infect itself and in turn inoculate others. The author then described the life cycle of the organism similar to that of malaria found in the blood of birds and developing in the *Culex* mosquito. This growth is much more readily observed, because birds and this species of insect are both easily obtainable. He showed with the aid of many photographs the differences between the *Anopheles* and *Culex* mosquitoes, the infection of birds, that of the *Culices* and the later stages of development of the parasites, until that is reached in which the renewed inoculation of the birds is again possible. Further, the speaker discussed the epidemiological characteristics of the malarial diseases and showed how easily its dependence upon the presence of the *Anopheles* could be demonstrated. Notwithstanding this connection, however, there are two important points which still remain open to question. One is the fact that apparently fresh infections are found in regions which have no mosquitoes. The solution of this possible difficulty is that after careful investigation in such localities, the *Anopheles* mosquito has after all been found. This species is peculiar in hiding by day in cellars, houses, barns, stalls, etc., and swarming only at night. It is therefore much more difficult to find. Moreover, its bite is much less prominent and painful than is first of the *Culex* and can be easily overlooked. The other disputed point hangs on the fact that travellers through solitary wildernesses and marshes, where no human being has been, have been known to be stricken with malaria. The explanation of this interesting enigma probably is that the incubation of malaria may be a very long one, so that the real infection in such cases antedates the journey and the surroundings of the journey provoke the invasion. Again, it does not often happen that an expedition remains for a very long time out of connection with some human center, because, in order to carry only small quantities of provisions upon the various short extra journeys, the base must be reasonably near the abodes of man. Koch's findings, which have been fully established by the English, show that the vast majority of the natives, especially the children, are the victims of chronic infections. For the conquest of malaria three different methods are suggested, namely, the British, the Italian and the German. At the outset one must give up any idea of eradicating the disease by destroying the mosquitoes in the affected localities. The Italians have recommended the use of screens in the houses and of protective clothing. These have accomplished much in Italy and Koch has acknowledged that they cannot be useless. But probably Koch would be the last in a malarious district to envelop his sleeping quarters with netting. While in Italy this method of protection must be observed only during a few hot months, if one were to carry out logically the Italian ideas in the tropics, he must year in and year out subject himself to the personal discomforts and sanitary hindrances of it, too little ventilation at night, difficulty in moving about and increase of the heat in the summer. These are the primary objections to the Italian prophylaxis. The British regimen is that mosquito-nets should be employed with judgment in houses and clothing according to the locality and the season. They, however, go one step farther and recognize that the natives in a malarious country are the real hosts of the parasites and the true source of the danger. Consequently, they argue that there should be as wide a separation in every way as possible, dwellings, mercantile and household relations, etc., between the Europeans and the aborigines. This can be carried out to a limited extent, but has many difficulties and obstacles. Its chief weak point is that it leaves the malaria to continue its ravages among the natives unheeded and unchecked. The German plan, which Koch thought out and first formulated, rejects both the points of the British and the Italian investigators and aims to strike at the cause of the trouble, the malarial organisms

themselves. The blood of the natives is taken and examined for them, and such as are carrying the parasite and menacing public welfare are treated with quinine till they are cured and the source of danger removed. Koch recognized the great difficulties in the way of such a plan in a populous place, but on no other basis could he explain the reclamation of such formerly malarious localities as Hongkong, Batavia, etc. It is likely that in any place the regular, persistent, and painstaking administration of quinine would in the long run entirely eradicate the disease.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held Thursday, May 2, 1901.

The President, Robert F. Weir, M.D., in the Chair.

This meeting was held under the auspices of the Section on Surgery.

Portraits of Æsculapius, God of Medicine.—Dr. Charles L. Dana, one of the Vice-Presidents of the Academy, presented a series of photographs of the statues and temples of Æsculapius, the divine patron among the Greeks of Medicine and Healing. Some time ago Dr. Dana was asked where a copy of the portrait of Æsculapius could be found. His interest in the subject was aroused and has resulted in this collection. It includes photographs of all the types in which artists have created Æsculapius' features. The best statue of Æsculapius from an artistic standpoint was found in Melos not far from where the statue of the Venus de Milo was unearthed. This deserves to be called the Æsculapius de Milo and is of the very best Greek art. If not Phidian, it is the creation of a disciple who was very near Phidias. This type has been repeated with shades of difference a number of times. The next best statue of Æsculapius is that of Myron in the museum at Florence. This is also an excellent work of art, artistically only a little lower than the Phidian types. A third group of Æsculapian reproductions are found at Epidaurus near the temple of Æsculapius. Most of these are bas-reliefs. A fourth series of portrait statues of Æsculapius are late Greek or Roman in origin and are of a distinctly lower order of art. In the later statues the godlike calm of the countenance of the God of Medicine is replaced by the sorrowful, troubled features of the human physician, anxious about his patients. Many of the Roman statues of Æsculapius resemble Roman emperors and it is not always easy to distinguish them.

Temple of Æsculapius at Epidaurus.—The temple at Epidaurus existed from about 500 B.C. and was not without votaries until at least 300 A.D. The best-known temple was built about 380 B.C. For its construction, bids were advertised throughout the cities of Greece, quite as in modern times. Sixty contractors performed different parts of the work. The architect of the structure received about eighteen cents a day, good wages in those days. It took about five years to build and cost about $35,000 in our money, which represented nearly ten times as much in the money of that time. The temple was not large, about eighty feet by forty. It was especially famous for the handsome sculpture and decorations it contained. Several buildings were attached to the temple, all of them situated within the sacred grove of Æsculapius. There was a rotunda, within which was the sacred spring. There was a dormitory attached to the temple in which devout visitors slept in order to receive in dreams the directions of the God of Medicine with regard to the management of their health. The walls of the dormitory were lined with the votive tablets of those who felt that they had been benefited by the dream suggestions of the gods. The priests were supported and the temple was kept up by the offerings of devout clients of Æsculapius who came to Epidaurus for their health.

Theater at Epidaurus.—Situated at some little distance from the temple was the famous theater, the second largest in Greece. People who came to take the waters of Epidaurus at the sacred spring, to wander through the sacred grove and to live for a time in its quietude, did not neglect the benefits that might be derived from pleasant relaxation. The theater at Epidaurus was famous throughout Greece and was very well attended. It is evident that advantage was taken of all natural means of benefiting health at this old-time health resort and that, as in our modern health resorts, it was realized that relaxation for the mind would do much to benefit bodily ills. Not very much of the temple remains, but sufficient was unearthed about fifteen years ago to enable Greek scholars to restore on paper the temple of Æsculapius and the surrounding buildings as they existed in the olden times. Plans of the façade of the temple and of the interior of the rotunda and the dormitory, with a photograph of Epidaurus as it now appears, were also presented to the Academy by Dr. Dana.

Acute Intestinal Obstruction.—Dr. Howard Lilienthal read the paper of the evening on this subject. It concerned only the clinical aspect, that is, the diagnosis and treatment of the more acute forms of intestinal obstruction. This class of cases has a very high mortality. Death does not, however, take place from retention of feces, for there are many people of constipated habit, who have a movement not oftener than once a week and yet suffer very little inconvenience in their general health. When intestinal obstruction occurs, grave symptoms begin to develop almost at once.

The principal reason for this is the interference with the circulation in the intestinal wall. There are, however, other good reasons. One of the principal ones is the shock incident upon the strangulation of a vital organ. As the stasis in the gut becomes more marked even where peritonitis does not develop, spots of ulceration may occur on the serous surface and gangrene may result. As a consequence of the lowered vitality of the intestinal walls infectious micro-organisms readily find their way out of the gut and the peritonitis develops. The distention of the intestines with gas leads to interference with the heart action and also with respiration and this causes further symptoms and adds distinctly to the danger of the case.

Fatality of Intestinal Obstruction.—True intestinal obstruction is very fatal. According to a good authority, four thousand deaths per year occur in Germany alone from this cause. The same authority inclines to the view that only neuropathic cases of ileus recover. So-called medical cures take place in cases in which there was never any real intestinal obstruction, but only a spasmodic condition. These cases instead of being subjects for congratulation are really more harmful than beneficial. They perpetuate the idea that medical treatment may do some good in genuine intestinal obstruction.

Causes of Obstruction.—Sometimes the adhesions that form between portions of the intestine after an operation cause the obstruction. A case of appendicitis may be operated upon, free pus evacuated, and some weeks later intestinal obstruction may occur. In such cases it must not be forgotten that multiple obstruction may occur and the surgeon must assure himself that while relieving one obstruction he is not overlooking others that may continue the symptoms. In one case Rehn found a gauze compress blocking the gut. He concluded that this had been left in the peritoneal cavity after a preceding operation and had ulcerated its way into the intestine. It is possible, however, that it might have been swallowed.

Prophylaxis of Adhesions.—In order to avoid the formation of adhesions between intestinal coils after operation, the surgeon should exercise great care in handling the gut and not too much of it should be exposed. Deaver is inclined to think that appendicitis is often mistaken for intestinal obstruction. However. there seems no reason to doubt that intestinal obstruction is more frequent after peritonitis. Whenever there is any localized point of sensitiveness in the abdomen, no matter where it may be situated, it is well to think first of appendicitis.

Symptomatic Course.—Vomiting is one of the earliest and most characteristic symptoms of intestinal obstruction. When the obstruction is tight, the vomit may be projected for some distance. The nearer the obstruction is to the stomach, the sooner will vomiting occur, the more is the shock to the system and the sooner is relief required. The passage of foul gas is of more importance as a sign that the obstruction has yielded than the passage of feces. Some feces may be retained below the obstruction for some time. As a rule, fecal vomiting must not be waited for to confirm the diagnosis. This symptom usually comes too late in the course of the disease for operation to be successful.

Treatment Before Operation.—In adults in whom the symptoms of intestinal obstruction are not very acute and have not lasted long, an enema may be tried and a small injection of morphine given to relieve pain. A large injection of morphine will always mask the symptoms and do more harm than good. A second dose of morphine should not be given. Cathartics are always dangerous. If the patient has been of constipated habit and there have been no stools for several days before the symptoms of intestinal obstruction develop, a large enema is indicated. Important symptoms of genuine intestinal obstruction in contradiction to fecal impaction are the occurrence of ischuria and mouth-dryness. The latter often becomes a very troublesome symptom and it is one that can be depended on for more diagnostic significance than is usually attributed to it.

Atropine Treatment.—Notwithstanding the fact that atropine makes the mouth dryer and so adds to the patient's annoyance, it is sometimes used to overcome the spasm on which the intestinal obstruction depends, or, at least, so to relax the muscular walls of the intestines that Nature has a chance to overcome the obstruction. German observers have reported series of cases in which atropine has proven very satisfactory. In one case as much as ten milligrams have been given. It is claimed that it is antispasmodic and is also tonic in paralyzant conditions of the intestine. It must be given to the verge of delirium. It does more good in chronic cases than in the acute variety. It is extremely doubtful if it ever does any good after stercoracious vomiting has once set in.

Widal's Serum for Intestinal Obstruction.—A very interesting suggestion has come from Professor Widal of Paris with regard to treatment for intestinal obstruction. He considers that the constitutional symptoms of the condition are due to toxins in the blood as the result of the lowered resistive vitality of the intestinal wall due to stoppage of the circulation. He thinks that there should exist in the normal intestinal wall of animals some substance that would neutralize these toxins. He has succeeded in obtaining an animal extract which has given satisfaction in relieving the symptoms of artificial intestinal obstruction in animals. His scheme of therapeutics seems

eminently theoretic and yet considering his authority it must receive due weight.

Danger of Massage.—Massage is often suggested as a remedy for intestinal obstruction. Its employment in very acute cases where considerable changes have taken place in the intestinal walls would probably be followed by a fatal result. There are cases in which massage may do good. These are mainly of the spastic variety of intestinal obstruction, or at the very beginning of subacute cases. One case has been reported where two operations for intestinal obstruction were done and in each case a spastic contraction of the gut was found, so that the diameter of the intestine was scarcely more than that of a lead pencil. At both operations relief was afforded by forcing the contents of the gut, through this narrow lumen and overcoming the spasm.

Technic of Operation.—Dr. Lilienthal has had 41 per cent. of recoveries in his operative interventions, although many of the cases were in almost hopeless condition when the operation was undertaken. From his experience the following technic is advisable: The stomach should be washed out before operation is begun and even before the anesthetic is given. In the worst cases no general anesthetics should be given. The operation can be very well done under local anesthesia. When there is doubt as to where the incision should be made, a small incision that will admit one or two fingers should be made in the right iliac region. It is here, in the vicinity of the appendix, that the great majority of intestinal obstructions occur. If the obstruction cannot be located at once, a long median incision should be made. It is important to relieve the constriction as soon as possible, and the possibility of the presence of multiple obstructions must not be forgotten. The distention of the gut should be relieved by punctures in it opposite the mesenteric attachment which will give vent to the gas and to feces if necessary. Enterostomy should not be done unless a fatal termination is threatening. Little is to be gained by a cathartic after the operation if the obstruction has been well relieved.

Slight Advance in Surgery for Obstruction.—In discussing Dr. Lilienthal's paper. Dr. B. Farquhar Curtis said that the first public discussion in which he ever took part concerned intestinal obstruction. Notwithstanding the great advancement in surgery during the last twenty years, the successful treatment of intestinal obstruction is still far from being in a satisfactory condition. Patients do not come for operation any earlier than was the custom. Non-acute obstruction is relieved by medical means and the temptation is to wait too long before applying to the surgeon. It is still the common experience of surgeons to get moribund patients, cyanotic, and with intensely distended abdomen.

Progress in Symptoms.—To the symptoms of intestinal obstruction only one has been added within the last fifteen years! This is the presence of leucocytosis as an indication of peritonitis, or of threatening infection of the peritoneal cavity. Although it may seem conventional, the question of differentiation of intestinal obstruction and of strangulated hernia must still be discussed. Not long ago Dr. Curtis was asked to see a patient who had suffered from left femoral hernia, but this had not been down for two years. The patient was stout, yet not overstout. No swelling could be detected in the thigh where the femoral hernia should be looked for. At operation a small strangulated hernia was found, already gangrenous. This was reduced from within, but the patient did not recover.

Despite the advance in medicine and surgery, it is still difficult, if not impossible at times, to differentiate such conditions as pancreatitis and thrombosis of the mesentery gland from intestinal obstruction. When patients are old, malignant disease must always be thought of as the cause of symptoms of obstruction. It is possible for an annular stricture in cancer cases to have a very small lumen and yet produce no symptoms. This becomes plugged by some bit of indigestible material, or loss of power occurs in the gut just above the stricture and feces fail to pass. This condition of affairs will give the symptoms of acute intestinal obstruction very readily. In volvulus the presence of a localized tumor is of great value in indicating the site of the obstruction and showing where the incision should be made for operation.

Rectal Examination.—A precaution that is sometimes neglected and can not be too much insisted on is digital examination of the rectum, as soon as difficulty in defecation occurs. Very often the supposed intestinal obstruction will be found to be due to some pathological condition that can be reached very easily by the examining finger in the rectum. The general practitioner is especially prone to neglect this means of diagnosis.

Operative Technic.—The washing out of the stomach before operation is a great gain. Unfortunately the general practitioner uses this method in order to delay operation and the patient comes to the surgeon when exhausted beyond all hope of relief. As a rule the incision should be made in the median line, because this is more generally advantageous, unless there are distinct localizing symptoms.

Enterostomy.—Dr. Curtis asked leave to say a word in favor of the much-abused operation of enterostomy. It is of great value when patients have been very much weakened by preceding severe symptoms. It shortens very materially the time of operation and relief is afforded as soon as the opening is made. In most cases the artificial anus closes of itself. For enterostomy local anesthesia may be used

much more easily. Then the surgeon may wait until the patient is in better condition for further operative intervention.

Intussusception.—Dr. Charles L. Gibson said that this phase of intestinal obstruction deserves special attention. The mortality of intussusception jumps after the second day from 39 per cent. to 61 per cent. The condition must be relieved then as soon as possible. The septic condition that supervened very soon carries off the patient unless something is done for its relief. If gangrene threatens a portion of the intestine, enterostomy should not be done in the part of the gut the vitality of which has been suspiciously lowered. It is very hard to recognize portions of the intestine that are thus affected from external appearances only. With regard to the location of the obstruction, certain points help one to determine it. If there have been any symptoms of appendicitis, usually the obstruction will be found to exist in the left iliac region. In women, if there have been any gynecological troubles, obstruction usually takes place in the pelvis and a median incision low down must be made. Other circumstances enable us to locate and diagnose the trouble in special cases. Ileus is more liable to take place in old people and it is in this class of patients that pathological conditions consequent upon gall-stones are apt to set up intestinal obstruction.

Medical Views on Intestinal Obstruction.—Dr. Morris Manges said that the only medical treatment of acute intestinal obstruction is surgical intervention. The results of operation are not so discouraging as they were. Mikulicz reports 70 cases with 34 recoveries. It is the medical man's duty to diagnose intestinal obstruction as early as possible and then send for the surgeon. If the medical man waits until the classical picture of intestinal obstruction develops, very little hope is left for successful surgical intervention. The more classical the diagnostic picture the less the chance for recovery. Vomiting and shock are the early characteristic symptoms. Stercoraceous vomiting must not be waited for. A too fine diagnosis is dangerous. Extreme distention of the abdomen makes diagnosis very difficult. The importance of rectal examination cannot be too much insisted on. The symptoms of developing intestinal obstruction may be very insidious and deceptive. Passages of gas may occur, yet there may be no relief afforded to the symptoms and the patency of the stricture is not indicated. More important than the presence of gas in the rectum is the foulness of the gas that is given out. Indicanuria has its significance. An early and more important symptom is the presence of albumin, if it is known that it was not present in the urine before. This forms an important symptom of beginning peritonitis. Drugs very seldom do much good and their administration, as a rule, only serves to delay operations and to increase the danger. Large doses of atropine have been given, but it is doubtful if they ever did good. One-twelfth of a grain of atropine does not produce very enviable feelings in the patient. It seems probable that the cases in which the atropine treatment proved favorable have been reported. The others, in which it did no good, were passed on to the surgeon and failed to be reported by the medical man. The employment of atropine has proved useless at Mt. Sinai Hospital. One of the important symptoms is the reflex nervous shock. The septic condition that develops also affects the nervous system and adds to the depression.

Kehr's maxim with regard to intestinal obstruction deserves to be remembered. He says: "It takes less courage to recommend a surgeon in a case of intestinal obstruction than to attempt to treat the case medically."

Intussusception in Children.—Dr. Koplik said that the symptoms of intussusception in infants often do not develop suddenly, but insidiously. They often seem to point to the presence of an acute catarrhal gastritis, and the differential diagnosis becomes very difficult. In children, particularly, vomiting may occur and then disappear for twelve hours, or more, before reappearing again with beginning collapse. Even bloody vomit may occur, stop completely, and then recur. For the diagnosis of intussusception careful abdominal examination is very necessary. As the belly muscles are tightly distended in order to perform this examination satisfactorily an anesthetic must be given. In children, more than in adults, a rectal examination is very necessary. Whenever the presence of intussusception with intestinal obstruction is suspected, the physician should not wait for fecal vomiting and should not depend on intense prostration to give the relaxation which makes examination and diagnosis easier. In children, particularly, the case may prove fatal before fecal vomiting develops, or even before ordinary vomiting becomes serious.

Dangers of Enemata.—Dr. Robert F. Weir said that the important cause of general symptoms in cases of intestinal obstruction is the septic condition that develops. This must be relieved as soon as possible. After this the shock to the patient from the interference with the circulation and function of an important organ is the most serious element. The shock and septic condition are rendered much more serious in their effects by the increase in intra abdominal pressure. This interference with respiration and heart action adds to the danger of collapse. The distress may be largely increased by the administration of large enemata. Abuse in this matter must be carefully looked for. In one case under Dr. Weir's care an intestinal obstruction proved to be due to an old appendicitis, but many of the serious symptoms in the case were aggravated by an immense collection of water which had been

forced into the colon by injection. When enemata are given, they should not be repeated, unless there is assurance that most of the former injection has come away. As a rule, in the intervals betwen injections a long tube should be left in the rectum in order to relieve the pressure produced by an accumulation of water.

Spontaneous Relief in Intestinal Obstruction.—Dr. Sells reported a case of a woman of twenty-three, not very tall, weighing 235 pounds, who suffered from obstinate constipation. Symptoms of either an impaction of feces or an occlusion of the bowel developed and large quantities of olive oil were injected, a pint a day for several days. A spontaneous opening occurred through the umbilicus from which a large quantity of feces was evacuated. The case has always seemed to Dr. Sells obscure in its pathology, though he inclines to think that it was a case of intussusception with a contraction of adhesions to the abdominal wall.

Practical Points.—Dr. Lilienthal in closing the discussion said that where there is doubt as to the location of the obstructive lesion of the intestines, it is well to make a small incision in the right iliac region, just sufficient to admit one or two fingers. In the majority of cases the obstruction will be found in this portion of the abdomen. If it is not, nothing is added to the shock and no harm is done. The classical median incision may immediately be made and the operation proceeded with.

With regard to children it must be remembered that, while they bear the shock of intestinal obstruction badly and may die before their symptoms develop to the classical picture of intestinal occlusion, they bear operations very well. Certainly in this class of cases operations should be done much sooner than is usually the custom. It is much better to disturb the family by the suggestion that a surgeon should be called in early in the case than to endanger the little patient's life. Too much stress is laid on the fact that the friends of patients are disturbed by the suggestion of surgical interference. This is a relic of the time when operations upon the abdomen were practically a last resort and when they were done only with a forlorn hope that the patient might possibly be saved. Needless to say, the present standpoint of physicians and surgeons with regard to abdominal operations is very different to this.

BOOK REVIEWS.

THE AMERICAN YEAR-BOOK OF MEDICINE AND SURGERY. Under the General Editorial Charge of GEORGE M. GOULD, M.D. Surgery. W. B. Saunders and Company, Philadelphia and London.

THE present is a worthy addition to this excellent series which has attained a well-deserved popularity with the profession. The plan adopted last year of issuing two volumes, one devoted to medicine and the other to surgery, is continued and the list of contributors remains practically unchanged. The volume is adequately illustrated and well indexed, while all the more important articles receive brief editorial comments which the eminence of their writers makes well deserving of consideration.

THE TECHNIQUE OF SURGICAL GYNECOLOGY. Devoted Exclusively to a Description of the Technique of Gynecological Operations. By AUGUSTIN H. GOELET, M.D., Professor of Gynecology in the New York School of Clinical Medicine. International Journal of Surgery Company, New York.

THIS book, as the title and preface declare, is devoted exclusively to the technique of gynecological operations. The indications for any particular operation in a case in which there might be a choice of several procedures are not discussed. Indeed, the volume is so limited in its scope and so exclusively personal in its character that it might well have been entitled "The Author's Technique in Surgical Gynecology." The preparation of the patient for operation is clearly and forcibly presented in the first chapter and its importance is wisely emphasized. Then follow chapters on preparation of the field of operation, preparation of the operator, operating room, etc. These descriptions are in line with the conventional methods now universally used. To this there is no objection, but when we approach the chapters descriptive of the operations we miss the air of broad surgical principles that should breathe through such pages, and find ourselves confined to the mechanical details of work done by the author's two-branched or four-branched dilators, the author's dull or sharp curette, the author's double-cutting-edge trachelorrhaphy knives, etc., etc. This is too narrow, too mechanical. No special knife is necessary for the performance of trachelorrhaphy, if the operator understands the principle of the operation and the essentials to success. The same remark applies to all the gynecological procedures. Special instruments, of course, are necessary, but slight modifications of established instruments for the purpose of meeting an individual operator's fancy and enable him to attach his name thereto are not of sufficient importance upon which to base an operative manual. Such is the fundamental weakness of the book under discussion. In addition to this there are numerous minor errors of technique and not a few major points open to criticism.

In the chapter on the care of patients after operation the author shows that he is a good nurse, resourceful and attentive. Definiteness of statement and fulness of detail must be the saving features of a book upon this subject, but the statements must be accurate and the details justified by experience.

CLINICAL PATHOLOGY OF THE BLOOD. A Treatise on the General Principles and Special Applications of Hematology. By JAMES EWING, A.M., M.D., Professor of Pathology in Cornell University Medical College, New York. Lea Brothers & Co., New York and Philadelphia.

THE enthusiasm with which the study of the blood has been taken up by clinicians, as well as laboratory workers, has been more than justified in the gaining of an immense amount of practical information. In order to keep pace with the rapidly accumulating facts which have practical, as well as theoretical, importance a number of excellent manuals have appeared in English and in foreign tongues. We confidently believe that the volume under consideration merits high praise and is to be considered the latest and best word on the general subject.

The study of hematology is bound to be one of the most important aids in medical diagnosis. Without it, in many cases, the practitioner stumbles along, without any idea of the fundamental trouble in many an involved and complicated condition. We know of no more practical and reliable guide than the present work. It is complete, exhaustive, accurate, and exhibits good judgment in the interpretation of the many studies made by numerous investigators.

The work is further commendable from the illustrative standpoint and for bibliographic completeness. The "up-to-date" man belies such characterization who does not take advantage of the important facts which are here collected and arranged for him.

EXPERIMENTAL PSYCHOLOGY. A Manual of Laboratory Practice. By EDWARD BRADFORD TITCHENER. Vol. I. Qualitative Experiments; Parts I.-II. Students' and Instructors' Manual. The Macmillan Company, New York.

THE present work typifies that tendency of modern psychology to get as far away from speculative interpretations of Nature's processes as possible. It is eminently a work dealing with experimental methods and, as such, one of the best in the English language.

The author has avoided, and we believe very wisely, the usual text-book style of definitions of psychological phenomena and has substituted a carefully arranged schedule of experiments, mostly with self-made apparatus, which affords the student, in the carrying out, the best type of observations concerning the essential features of the psychical processes involved.

We commend this manual most cordially to student and to teacher alike. To the neurologist and alienist the experiments in sense perceptions would prove suggestive and valuable.

A LABORATORY GUIDE IN ELEMENTARY BACTERIOLOGY. By WILLIAM DODGE FROST, Instructor in Bacteriology, University of Wisconsin. Published by the Author. Madison, Wisconsin.

THIS work consists of a book of laboratory sheets specially prepared and graded for the student of bacteriology. It constitutes note-book and text-book in one binding and as such is to be recommended. It deserves a wide use, as it is thorough, systematic and very carefully planned and worked out.

ESSENTIALS OF THE DISEASES OF CHILDREN. By WILLIAM M. POWELL, M.D. Third Edition, Thoroughly Revised by ALFRED HAND, JR., A.B., M.D., Dispensary Physician and Pathologist to the Children's Hospital, Philadelphia; Bacteriologist, the Bryn Mawr Hospital; Pathologist to St. Joseph's Hospital. Philadelphia and London, W. B. Saunders and Company.

WE are inclined to condemn the use of quiz-compends as leading students to study facts parrot-fashion with neglect of more complete works on the subject, yet in certain schools the compend is a popular book, and, if it must needs be, we cannot help feeling grateful if it is carefully compiled by competent men from the best works. In the past few years the advances in pediatrics and infant-feeding have been rapid and extensive, and this new matter has not been forgotten in this revision. Numerous excellent prescriptions have been included, the metric system, however, being completely ignored. Splenic anemia is not mentioned, and in modifying milk for artificial feeding, cow's milk is assumed to contain 3.5 per cent. of fat, a low percentage.

BOOKS RECEIVED.

The MEDICAL NEWS *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* MEDICAL NEWS *will shortly appear.*

ANÆSTHETICS AND THEIR ADMINISTRATION. A Text-Book for Medical and Dental Practitioners. By Dr. F. W. Hewitt. 8vo, 527 pages. Illustrated. The Macmillan Company, New York.

HOW TO COOK FOR THE SICK AND CONVALESCENT. Arranged for the Physician, Trained Nurse and Home Use. By Helena V. Sachse. 12mo., 239 pages. Illustrated. J. B. Lippincott Company, Philadelphia.

THE HYGIENE OF TRANSMISSABLE DISEASES: THEIR CAUSATION, MODES OF DISSEMINATION AND METHODS OF PREVENTION. By Dr. A. C. Abbott. 8vo, 351 pages. Illustrated. W. B. Saunders & Company, Philadelphia and London.

PROCEEDINGS OF THE NINTH ANNUAL MEETING OF THE ASSOCIATION OF MILITARY SURGEONS OF THE UNITED STATES. 8vo, 507 pages. R. R. Donnelley & Sons' Co., Chicago.

DIE SERUM BAKTERIENTOXIN UND ORGAN-PRAPARATE. By Dr. Max v. Waldheim. Demi 8vo, 404 pages. V. Hartleben, Wien, Pest, Leipzig.

PRACTICAL SURGERY. For the General Practitioner. By Dr. Nicholas Senn. 8vo, 1,133 pages. Illustrated. W. B. Saunders & Company, Philadelphia and London.

ESSENTIALS OF THE DISEASES OF THE EYE. By Dr. E. Jackson. 12mo., 261 pages. Illustrated. W. B. Saunders & Co., Philadelphia and London.

REPORT OF BOARD OF HEALTH AND BOARD OF CHARITIES OF PORTO RICO. 8vo, Washington.

VOL. LXXIX. NEW YORK, SATURDAY, AUGUST 3, 1901. NO. 5.

ORIGINAL ARTICLES.

INJURIES OF THE HEAD IN THE NEW-BORN.

BY ANDREW F. CURRIER, M.D.,
OF NEW YORK.

THE importance of this class of injuries is measured, not merely by the immediate damage to the head or soft parts of the skull, but by the possibilities of death as a near or remote result, by the possibility of life-long defect or deformity, and especially by such detrimental effect upon the structure of the brain, which effect cannot always be analyzed or explained, that development is arrested or prevented, the individual manifesting mental incompetence in any degree from slight backwardness to hopeless idiocy. The significance of the lesions which may be received is not fairly appreciated by the medical profession and this gives increased importance to the subject.

Notwithstanding the fact that these lesions are immediately fatal or fatal within a few hours or days, in very many cases it is a rare occurrence that a careful postmortem examination be made except as an occasional incident in a public institution. There is an abundant literature of cases in which injury to the skull has taken place, but comparatively few in which the exact pathological condition has been studied.

No one will deny that the obstetric forceps are used far more frequently than they were a generation ago. The result has been, on the whole, favorable to safe delivery and subsequent well-being of the child, but a train of evils has also attended the use of this beneficent instrument, including its untimely, or injudicious or unskilful application with occasional destructive results to the mother and very frequent damage to the child, its head being bruised, the bones fissured or fractured, the blood-vessels torn and the brain compressed.

It would seem desirable that the writers of textbooks on obstetrics should more cogently express the great possibilities of harm to the child's head from this means not less than from the failure to take advantage of it at the proper time.

The injuries which are under consideration may be received during natural labor or during artificial or assisted labor. They may involve (1) the parts external to the cranium; (2) the bones of the cranium; (3) the structures within the cranium. They may result (*a*) in immediate death; (*b*) in death after a few days or months; (*c*) in recovery, but with permanent lesions of the skull, and possibly with such injury to the brain that mental development may be permanently retarded or wholly checked and paralysis render certain areas of the body useless or ineffective; (*d*) in recovery with disappearance of all evidence of the injury received.

Concerning the injuries received during natural labor the cause must usually be a disproportion between the fetal head and the maternal pelvis. The head may be very large, at least relatively to the dimensions of the pelvis; it may be hydrocephalic; the fontanelles may be small; the bones may be unusually hard and ossification so far advanced that opposite sides will not overlap in the process of molding, which is the conservative element in many tedious and difficult labors. Also the skull may be asymmetrical, one or more bones of one side being much larger or smaller than their fellows upon the opposite side.

In many of the recorded cases, especially those in which the skull has been deeply indented, the fault has been clearly attributable to a too prominent sacro-vertebral angle or sacral promontory, whether caused by the improper relations of the bones to each other or by an outgrowth or exostosis either at this point or elsewhere in the pelvis. The pelvis itself may be contracted, irregular or rachitic and prohibit the ordinary mechanism of labor. Rarely the fetal skull may be injured in connection with a lesion sustained by the mother during her labor, or even during the course of pregnancy, such as a blow or a fall, or by a sudden precipitate labor in which the child is hurled outward into the world by a tremendous pain, landing upon its head and bruising or crushing it.

Blot[1] reports a case in which a woman jumped from a window while in labor, breaking her pelvis. A dead child was delivered with forceps. Both parietal bones were found broken. The fracture was recognized before the application of the forceps.

Casper[2] reports a case in which the cranium of a rachitic child was fractured during labor. There were evidences of other fractures which had been received during fetal life. There had been cerebral and meningeal hemorrhage. The labor was easy, the head soft and membranous. Death occurred in eight hours.

Perry[3] reports a case in which a child's scalp was lacerated from the right parietal across to the left, the bones being exposed. Exfoliation occurred, leaving the brain exposed over an area as large as half a dollar. The labor was natural, though a very severe one.

In rachitic children in whom the bones are badly developed and imperfectly ossified, fracture may take place *in utero* or in connection with a labor so easy that the mother is scarcely conscious of pain. The fracture may also be attended with copious hemorrhage.

A large head in a small pelvis, or even a nor-

mal head in a nearly normal pelvis, may be retained so long that the brain will be dangerously compressed. This is not an infrequent occurrence when the uterine contractions are indefinitely suspended in connection with the uterine inertia. Such cases were far more frequent in the past than now, the labor being allowed to linger for days rather than interfere with what were suposed to be the legitimate efforts of Nature.

A skull which has been compressed by such prolonged incarceration may resume its proper contour after a longer or briefer period of time and give no outward evidence of injury, but it is quite probable that if the sensitive brain has undergone compression to a considerable degree for many hours the result will be disastrous to the child, imbecility or idiocy being the consequence. Of course, the effects of this injury may not be apparent for months or even years. In cases of this character the effects of hemorrhage may also be disastrous, the blood escaping through an opening in the scalp, or forming a tumor under the scalp, or the pericranium, or effusing and coagulating within the membranes or within the substance of the brain itself. It is largely to the credit of modern gynecology that these terrible accidents have become less frequent, for, by the advocacy of the timely use and proper application of the forceps or other suitable instrumental procedures, it has indicated the way to anticipate and obviate them, while it has at the same time brought relief to the troublesome injuries to the maternal soft parts, which were so common when labor remained unassisted for several days.

Concerning the injuries which are received during artificial or assisted labor, such injuries may be unavoidable from the peculiar circumstances in a given case, or they may be the result of carelessness or ignorance, or a want of skill on the part of the accoucheur or midwife. The forceps may be badly applied, lacerating the tissues of the mother as well as those of the fetal head, traction may have no regard for the pelvic axis, or the requisite degree of force, or the disturbing effect which it is likely to produce upon both the maternal and fetal circulation. Especially when the application of the forceps is made above the brim, are these conditions likely to be fulfilled. Probably the percentage of injuries and fatal accidents to the fetus under these conditions is greater than in any other operative procedure which is not distinctly and intentionally destructive. The injuries to the fetal head from compression with the forceps are also numerous and are often fatal even when the instrument is properly adjusted and is applied within the pelvic cavity. Whatever may be said to the contrary it is difficult to imagine the effective use of the forceps in a pelvis which is nearly or quite filled by a fetal head without compression of that head and the greater the disproportion between the head and the pelvis the greater must be the compression. With difficult extractions and extensive molding of the head, it is probable that we would very often find even in children who do perfectly well after the first few days of life, in addition to the ordinary *caput succedaneum,* an accumulation of fluid or clotted blood under the pericranium, between the meninges or into the substance of the brain itself. We would also find more frequently than is usually supposed fissures and fractures in the immediate vicinity of one or both of the parietal eminences, for these parts are brittle and in many cases only imperfectly ossified at birth and sustain such accidents with only a moderate exhibition of force. The operation of version, so useful when skilfully and successfully performed and so destructive when badly performed or performed in cases in which the conditions are unfavorable to success, has also its percentage of injuries to the fetal head.[4]

Attempts to rectify an unfavorable position of the head or face by the hands or by forceps may result in fracture of bones of the head or face with coincident hemorrhage, which may result fatally. Or the bones may be so soft that the fingers penetrate them and produce serious injury to the brain. Idiocy has followed such an accident.[5] In twenty-nine cases in which version was performed, the frontal bone was fractured six times.

A distinguished obstetrician caused compression of the cranium with a single finger while attempting to rotate a head in a narrow outlet. Epileptic seizures continued for six weeks, and these were followed by choreic movements which still persisted when the child was four and a half months old. The injuries which are possible from the injudicious use of ergot are frequently hinted at in the treatises upon obstetrics, but I do not recall any writer who has referred specifically to such injuries in individual cases. The tremendous expulsive force with which the uterine muscle is sometimes endowed, amounting in some cases, it is said, to one hundred pounds, is manifested in the cases of precipitate labor in which the child is hurled into the world as if from a catapult and usually loses his life in the procedure, the bones being fractured by the violence of the delivery, or crushed by striking stones or other hard objects after its expulsion from the maternal body. These cases are often, and properly, the subjects of medico-legal investigation. We can readily understand, with these facts in view, the force which may be added to the uterine muscle by the stimulation of ergot, and it is not strange that fracture of fetal bones should result from such overstimulation. Unfortunately there have been few reports of injuries of this kind, the reason being obvious.

Veit[6] reports a case in which seven grams of ergot were given in the course of a three-day labor, causing tetanic contraction of the uterus. A dead child was delivered with forceps. There was hemorrhage under the pericranium, overlapping of the parietal bones, loosening of the sutures and fissures in the right parietal.

Swayne[7] reports one stillbirth due to the violent action of ergot, and another due to ergot plus forceps.

The injuries which are under consideration may involve (1) the parts which are external to the cranium; (2) the bones of the cranium; (3) the structures within the cranium.

1. The parts which are external to the cranium. The injuries may occur in either natural or assisted labor. The simplest form of this kind of injury is that in which with increase of pressure, as the head advances in the pelvis, the circulation in the scalp is impeded and the watery elements of the blood are squeezed out of the vessels into the surrounding tissue, accumulating at the most advanced situation of the head, where the resistance is least and forming what is awkwardly termed *caput succedaneum*. This tumor, as every one knows, quickly disappears after labor has been completed, and the circulation of the scalp has resumed its usual conditions.

When the labor has been one of considerable severity, the cranial compression having been great, either from rapid propulsion through the pelvis, or from prolonged retention within the pelvis, or from great violence in the use of the forceps, blood-vessels within the scalp may be ruptured, while the tumor which precedes the head, and which, under ordinary conditions, contains serum, will now contain blood and certainly lend greater gravity to the situation, possibly becoming a serious menace to the life of the child. Absorption of the contents of this tumor may occur, or there may be suppuration and abscess, and sometimes sloughing of all the soft tissues with necrosis and exfoliation of the bone. Death frequently results from such severe lesions.[8] These tumors may not be apparent immediately after birth, and several days may elapse before the development ceases. Their size will vary with the quantity of blood which has been lost.

If the face presents, the tumor, whether containing serum or blood, may be upon the face and it may leave an impression upon the skin which will persist during life. The soft parts of the head and face are also the seat of bruises, lacerations, indentations, and depressions caused by the slipping or compression of the forceps-blades, the violent use of the hand in performing version, or in rectifying faulty position, the scraping of the tissues as the head advances or is pulled downward by the projecting sacral promontory, or by an outgrowth of bone in some portion of the pelvis.

Pressure, whether by the forceps or the walls of the pelvis, may also bruise or crush the nose, the eyes, the lips, or the ears, and produce deformities which will be permanent. An interesting class of injuries to the face are the so-called birth palsies of Gowers, one side of the face being usually affected by undue pressure with the forceps over one or the other branch of the facial nerve. Fortunately, such injuries are usually either of short duration, the vitality of the nerve being restored and with it the muscular force, or they accompany other more serious injuries which speedily result in the death of the patient.

2. The bones of the cranium. The bones may be indented, fissured, dislocated, or fractured. Of course, it is possible that any of the bones, either cranial or facial, may be injured, even including those at the base of the cranium, but those which are most frequently injured are the frontal and parietal. All forms of injury to the bones may occur as well in natural as in assisted labor. Prolonged compression either by the unyielding walls of the pelvis or by instruments is almost certain to produce depression of one or more bones at the sutures or fontanelles. The sutures may be quite generally displaced and the bones correspondingly dislocated. A bone may be depressed to the extent of half an inch, or even more. A depression which is produced slowly is not usually as serious as one which is produced quickly and is usually recovered from. A bone may be depressed and fissured or fractured as well, or it may be fissured or fractured or both without depression. Bones may be fractured or dislocated in labors which are almost painless. They may also be fractured during fetal life, undergo complete repair, while others may sustain fracture during labor.[9] A fracture may be single or multiple, simple, compound, comminuted, or depressed. Unequal pressure upon the two sides of the head or face with the forceps may fracture a single bone, repeated and unskilful efforts may destroy the integrity of several bones.

Petit[10] reports a case in which the forceps were repeatedly applied unsuccessfully, the upper and lower maxillæ and the malar bones being dislocated and the muscles torn and infiltrated. The face presented and there was prolapse of the arms and the cord. Version was attempted, the uterus was ruptured and the woman died undelivered.

When a woman is delivered in the standing or sitting position, and the child is forcibly projected a distance of two and a half feet or more, if the fall is upon the head, and upon a hard object, such as a stone or floor, the bones of the vertex are usually crushed and comminuted. The resistance which may be offered by the umbilical cord does not materially modify the result. The medico-legal importance of this matter is considerable.

Fissuring of the bones may take place after very slight exhibition of force, this being due in many cases to imperfect or immature ossification. It is prone to start from a projecting structure, such as a parietal boss, an orbital ridge, a frontal eminence, a malar bone, etc., and may radiate in various directions. It may exist alone or in conjunction with other and more serious lesions. When it is uncomplicated, it is probably a condition of no very great importance, in most cases.

An indentation or depression is a not uncommon lesion which varies within wide limits in extent and significance. It may be only a slight dent or furrow, or it may be a deep depression,

it may even extend from one side of the head to the other, especially in the frontal or parietal region. It is frequently spoon-shaped, taking the impression of the bony prominence along which the head has scraped its way. A condition of this character is almost certain to occur when there is an exostosis in any portion of the pelvis, or when the sacro-vertebral angle is unduly prominent. In the latter condition the head is usually detained above the brim, and the forceps applied at mechanical disadvantage must drag the head along the unyielding obstruction. It has been frequently noted and alleged in such cases that the mark of the forceps if present at all did not coincide with the indentation or depression. But there are cases in which the indentation is clearly due to the action of the forceps, especially those in which one blade is applied over the brow or the face.

Perry[11] reports the case of a child born after a natural but severe labor, in which the scalp was torn from the right parietal across to the left. The bones were bared and necrosis over an area as large as half a dollar left the brain exposed. The child was well when three months old.

3. The structures within the cranium. Such injuries are the most serious of all and, if not at once destructive of life, may produce such an effect upon the nervous system that mental development is arrested and idiocy, epilepsy, insanity or some form of paralysis becomes the heritage of the individual. When the cranial bones are greatly depressed the phenomena are those which are well known in connection with compression of the brain at any period, coma and death in the severe cases, epilepsy, convulsions and paralysis in those which are less severe. Many of these cases are quite amenable to treatment and respond to such measures as remove the cause of the difficulty.

If the bones are fractured and splintered the brain and its membranes may be lacerated with or without compression and with severe resulting consequences.

Trismus and tetanus in the newborn are probably attributable in most cases to such accidents which are seldom if ever unaccompanied by hemorrhage.

Hemorrhage within the cranium is perhaps the cause of more of the severe results which attend labor than any other. Hemorrhage of the scalp or face may be unaccompanied by internal hemorrhage, but internal hemorrhage is seldom unaccompanied by hemorrhage of the scalp, though there may be no visible tumor, no break in the skin and no outward discharge of blood. Great numbers of stillborn children die from this cause. Though there may be no outward evidence of such a condition autopsies have repeatedly revealed an abundance of blood and clots between the skull and the membranes, in filtrating the membranes, spread over the surface of the hemispheres, or diffused within the substance of the brain and its ganglia.

Elliott[12] gives the following occurrences of hemorrhage within the skull. (1) In every variety of labor even when all seems favorable. (2) After birth when everything seems to promise freedom from risk. (3) In all cases, even where premature labor has been induced to diminish this among other dangers. (4) In utero before labor has begun.

If the compression of the head has been long continued either by the pelvis or by instruments the veins within the cranium will usually be engorged, serum or blood being present in the cavity, in the membranes, or in the ventricles, and microscopical examination may disclose minute effusions of blood throughout a large portion of the brain substance. The great vascularity of the scalp and the frail structure of the cranial sinuses should furnish adequate admonition of the necessity for great caution in applying force to the cranium in the process of delivery. Should the head be detained long at the vulva, the neck being constricted, congestion and apoplexy may be the result.

Internal hemorrhage though insufficient to produce a fatal result may cause the same troubles which an apoplexy causes at any period of life, hemiplegia, convulsions, epilepsy, etc. As in apoplexies at other periods of life, the blood may be absorbed while the disastrous effects of pressure and destruction of brain tissue persist. Hemorrhage within the skull may be combined with hemorrhage into the spinal cord and its membranes, rendering the individual helpless should life continue. Those cases in which blindness, deafness and want of smell are congenital probably are due in at least a certain proportion of instances to hemorrhage within the ganglia which control these special senses.

The result of the injuries which are under consideration are (1) immediate death, (2) death after a few days or months, (3) recovery with permanent lesions of the skull and, perhaps, with such injury to the brain that its development is arrested, while certain portions of the body remain paralyzed and useless.

1. Immediate death. It is a difficult matter to state the precise percentage of deaths from this cause. In those cases in which the labor has been long and severe, the exhibition of violence very great, whether from instrumental procedures or from the attempt of Nature to force a large head through a small pelvis, or from the want of coincidence between the diameters of the head and those of the pelvis, the fetal mortality must always be large. When the skull is crushed by a fall or any other cause, when the hemorrhage within the cranium has been very great, immediate death is the almost inevitable result. This is especially true when bleeding occurs within the brain, the ganglia, or the ventricles.

In a series of 153 forceps cases reported by Swayne there were 23 stillbirths. Of this number 17 children perished from the pressure of the forceps or the maternal efforts, or both combined.

Schroeder[13] reports 65 cases in which there

were ovoid or spoon-shaped depressions of the cranium. Of this number 32 were fatal, 22 being dead at birth.

Fritsch[14] thinks that those cases in which fracture of the skull has occurred are usually fatal from hemorrhage.

2. Death after a few days or months. This class includes those who are hopelessly injured and also those in whom septic complications arise, which, in children who are defective in vitality, cannot be successfully resisted. The greater number of these cases are also hemorrhage cases which have been associated with fracture or depression of the cranial bones. The septic complications are manifested by diarrhea, eruptions of the skin, phlegmonous inflammations in various portions of the body, abscess of the scalp, bones, or brain, and possibly necrosis of bone and sloughing of the softer tissues. In this class may also be included those who have destructive lesions of the brain from the pressure of bone, or the pressure of effused blood, resulting in paralysis of wider or narrower areas of the body, or in abolition of one or more of the special senses. Of the 26 fatal cases in more than 60 reports of injuries to the head which have been analyzed in the preparation of this paper only five are recorded as stillbirths while in the remainder life continued for periods varying from a few minutes, or hours, or days, to the eleventh month.

3. Recovery with permanent lesions of the skull and perhaps with such injury to the brain that its development is arrested, while certain portions of the body remain paralyzed and useless. The searching investigations of modern surgery have traced many a case of idiocy, or imbecility, or periodical convulsions to a lesion sustained during birth. Cases in which convulsions are periodical and in which the mind does not develop with the growth and development of the body certainly demand careful examination with the view of determining their relationship to a possible injury at birth which may be manifested by depression of the cranial bones or some other lesion of the skull. The severer examples of persistent injury, apart from those in which the growth of the brain is checked, are those which suffer with hemiplegia, facial paralysis, blindness, deafness or want of smell. The depressions and indentations of the bones become less conspicuous as life progresses, but they may remain as permanent stigmata of an entrance into the world under great difficulty. Among the cases which have been analyzed and in which the result was reported there appears but one in which the marks remained until death, in the others they remained visible from six weeks to five years. In two there was facial paralysis the duration of which was not noted, in two there was hemiplegia, one of the two having already reached the thirty-seventh year, and in one there was idiocy.

Dauchez[15] mentions three forms of paralysis which attend difficult labor; (1) spontaneous from natural obstacles or deformities; (2) from traction, version, or forceps; (3) pseudoparalysis with dislocation of one or both upper extremities.

Parrot and Troisier[16] studied the condition of the facial nerve after paralysis from injury with forceps at the stylomastoid foramen. In some of the cases no lesion of the brain was found; in others there was hemorrhage under the scalp, inflammation of the meninges, or laceration of the sinuses which were filled with clots. Paralysis may not appear for a day or two after birth, and if the nerve is examined microscopically it will be found disintegrated and the seat of fatty infiltration. It was believed that renewal of the nerve-structure could take place with care of the degenerated muscles.

The number of cases in this class is very large. Slight injuries to the head are received by many infants during delivery, scalp wounds, pressure marks from forceps, depression of the nose, swellings of tissue, even paralysis of the face. The lesion being trivial, the duration of the bad symptoms may not exceed a few days. The *caput succedaneum,* when composed of serum alone is a well-known illustration of the fact that such injuries are very transient. It has already been stated that the case is far different when the tumor contains blood. Even when it is merely a tumor of the scalp with no effusion under the pericranium or within the skull, its disappearance may be a matter of weeks.

Most of the cases of facial paralysis are transient, the nerve being restored to its normal condition and resuming its function upon the muscles. Even the deep depressions of the skull are obliterated in most cases, and the evidences of injury which accompanied them are gradually outgrown. In five cases reported by Depaul in which the cranial bones were depressed, the depression disappeared in all cases, all the patients recovering. In five of the cases which were analyzed in connection with this paper there were no bad results.

The question of treatment in this class of injuries is not without importance and it is one to which comparatively little attention has been paid. It is probable that life might be saved in many cases in which the injury is overlooked or in which its seriousness is underestimated. There are also cases in which a judicious line of treatment might prevent lifelong illness, hopeless idiocy, or imbecility. In every case in which the labor has been severe or protracted the cranium should be carefully examined to detect a possible fissure, fracture or depression of the bone. Any treatment which may be necessary should be instituted as soon as possible after birth—within the first few days of life if the condition of the patient will warrant it. Three cases are recorded among those which have been analyzed in which the scalp was incised, the depressed bone elevated and the patients' lives saved. In a fourth case the bone was trephined and elevated, a cure also resulting.

The principle seems to be a sound one that

these injuries are to be treated as nearly as possible as they would be treated at later periods of life, the same regard being paid to detail as would be proper and successful at any period of life.

The following brief conclusions were drawn from the study of more than 60 cases in which the skull was injured in the process of birth:

Indentations and depressions of bone showed 2 of the right frontal, 16 of the left; 5 of the right parietal, 9 of the left; 1 of the right temporal; 1 of the occipital and left parietal. The depressions varied from ½ inch to 2 inches long, ½ inch to 1½ inches deep, and ¾ inch to 1¾ wide. The marks and depressions disappeared in most cases in a few weeks or months, but in some cases they remained visible for years.

In 17 cases there were fractures of one or more bones. In 1 case there were extensive dislocations of cranial and facial bones. In 5 cases the bones were fissured. In 5 cases the scalp was more or less extensively lacerated. In 5 cases the brain was injured. In 4 cases there were injuries during fetal life.

There were 21 forceps deliveries, 3 high forceps, and 3 versions. There were 12 normal deliveries, and 7 labors were prolonged, the period varying between fifteen hours and six days. There were 3 precipitate labors. There were 6 cases in which there was tumor of the scalp. In 23 cases there was hemorrhage of one variety or another.

Of the abnormal presentations 2 were breech, 1 face, 1 face, arms, and cord, 2 occiput posterior. There were 5 cases in which there was coma and 6 of convulsions, 4 of paralysis, 1 of idiocy. In 24 cases there was deformity of the pelvis of one kind or another.

Death occurred in 26 cases from various causes. In 3 cases the scalp was incised and the bone elevated and in 1 there was trephining and elevation.

Typhoid Epidemic at Homestead.—More than 150 cases of typhoid fever are now in progress at Homestead, Penn. A special meeting of the Board of Health has been called to meet the alarming situation. Impure water is said to be responsible for the outbreak.

THE STATE OF THE GASTRIC SECRETIONS IN CHRONIC RHEUMATISM AND RHEUMATOID ARTHRITIS.*

BY FRANK H. MURDOCH, M.D.,
OF PITTSBURG, PA.

VERY little has been written regarding the state of the gastric secretions in chronic rheumatism and rheumatoid arthritis.

Bouchard[1] has seen swelling of the finger-joints associated with dilatation of the stomach, and Ewald[2] has observed numerous examples of gastric disturbance in patients with chronic articular rheumatism in which the dyspepsia was so marked that the pains in the joints were comparatively insignificant. Neither of these authors, however, make any mention of the result of an analysis of the stomach-contents. Einhorn[3] examined the stomach-contents of a patient suffering from rheumatoid arthritis and found achylia gastrica. In view of these facts, I trust that the report of the following cases may be of interest.

Case I.—On December 4, 1896, Miss McC., aged forty years, came to me complaining that for a year past she had been greatly troubled with insomnia, many nights being able to sleep only one or two hours. She also suffered from almost constant nervous belching, which practically confined her to the house. She looked pale and thin, had no appetite, and was altogether in a very miserable condition.

A physical examination revealed nothing wrong, excepting that the second joints of the first three fingers of the right hand were swollen and painful on motion. Examination of the stomach-contents made at intervals during a period of eight months showed sometimes an absence of free hydrochloric acid and at other times an excess of it, as follows:

Date.	Günzburg's Test.	Töpfer's Test.	Total Acidity.
Dec. 20, 1896	±	16	36
Jan. 10, 1897	+	52	66
Jan. 18, 1897	0	0	30
Mch. 6, 1897	+	16	65
Mch. 28, 1897	+	20	75
Apl. 16, 1897	+	18	74
May 13, 1897	+	15	74
Jun. 8, 1897	+	40	64
Jul. 6, 1897	0	±	16
Jul. 13, 1897	±	22	30
Jul. 20, 1897	+	24	44

This patient was given a diet to suit the changing condition of the gastric secretions, and had intragastric faradization and galvanization three times a week for some months. She made a complete recovery, and the swelling and pain in the finger-joints disappeared.

Case II.—February 1, 1897, Mrs. B., aged forty-two years, had been complaining at intervals for fifteen years of vertigo, bloating and belching, nausea, vomiting and insomnia. For two or three years past she had suffered greatly from pains in her arms and legs; and the first

*Read by title at the annual meeting of the American Gastro-enterological Association, Washington, D. C., May 1, 1901.

joint of the left forefinger was swollen and tender. Eight examinations of the stomach-contents were made during a period of ten months. Free hydrochloric acid was absent three times, normal twice, once in excess, and twice present in less than normal amount.

Date.	Günzberg's Test.	Töpfer's Test.	Total Acidity.
Jun. 18, 1897.....	+	26	58
Aug. 3, 1897.....	0	10	42
Sept. 8, 1897.....	0	10	52
Sept. 28, 1897.....	+	32	66
Oct. 30, 1897.....	+	40	64
Jan. 8, 1898.....	+	24	36
Jan. 13, 1898.....	0	0	20
Feb. 1, 1898.....	+	32	52

The treatment of this case consisted in a proper diet, and intragastric faradization used for several months. She made a good recovery, and the swelling and tenderness of the finger-joint entirely disappeared.

Case III.—June 12, 1899, Mrs. C., aged fifty-five years. For several years she had suffered from rheumatic pains in the middle joints of the fingers of the right hand, in the right wrist, and in her hips and knees. A month ago, one day after dinner, she became suddenly ill and was obliged to lie down. She had much distress in the stomach, with bloating and belching, and her hands and feet grew cold. She remained in bed two weeks, and is now very weak and has no appetite. Physical examination showed the chest intact, liver normal, stomach reaching two inches below the navel. The middle joints of all the fingers of the right hand are swollen and tender. From June 12, 1899, to December 22, 1900, a period of about eighteen months, six examinations of the stomach-contents were made. Twice free hydrochloric acid was absent, once it was in excess, and three times slightly below the normal.

Date.	Günzburg's Test.	Töpfer's Test.	Total Acidity.
Jun. 12, 1899.....	+	24	64
Jun. 23, 1899.....	0	8	64
Jun. 7, 1900.....	+	28	64
Jun. 26, 1900.....	+	48	68
Sept. 26, 1900.....	0	0	44
Dec. 22, 1900.....	+	28	56

On June 26, 1900, the pain and swelling had disappeared from the fingers of the right hand, but she had pain in the first joint of the little finger of the left hand and the joint was red and swollen. On September 26, 1900, the pain and swelling had disappeared from this joint also, and when I last saw her on December 22d, there had been no return of the rheumatism, and she was enjoying good health.

Case IV.—March 16, 1900, Miss F., aged twenty-four years, had complained for two years of being very nervous; often weeps without any apparent cause, her hair is very brittle, and is a foot and a half shorter than formerly on account of its breaking off. Has acne vulgaris on nose and chin; at times long red welts appear on different parts of her body, which last half an hour, and which burn and itch terribly. She had been constipated all her life, her bowels never moving without an enema. She often had severe pain in the right shoulder, which keeps her awake; and also pains at times in her fingers. Physical examination showed the chest intact, liver normal, stomach not displaced; all the second joints of the fingers of the right hand are enlarged, but not red or tender.

During March and April, 1900, I made three examinations of the stomach-contents, and found free hydrochloric acid in excess twice and below normal once, as follows:

Date.	Günzburg's Test	Töpfer's Test	Total Acidity.
Mar. 16, 1900.....	+	20	36
Apl. 5, 1900.....	+	36	56
Apl. 16, 1900.....	+	40	68

On March 31st, she came to my office complaining of pain in her right shoulder, which had kept her awake all night and from which she was still suffering. Intragastric faradization relieved the pain for two hours. Next day the same treatment relieved the pain for one hour. I then gave her ten grains of salophen every two hours, and the next day the pain had disappeared. I heard from this patient last week. She writes: "My rheumatism is almost gone. I have occasional attacks of it just as I have of indigestion. My finger-joints are still swollen, though no longer sore or tender." From this statement I take it that her rheumatism only troubles her when she is indiscreet in the matter of food or drink.

Case V.—September 3, 1900, Miss S., aged twenty-two years, had complained at intervals for four years of pain in her joints, mostly the large joints and especially the hips, although even the joints of her fingers have been affected, being tender at times to the touch. During the autumn of 1896 her ankle-joints became swollen, the swelling lasting two or three months. In January, 1897, she went to Hot Springs, Arkansas, and remained two months, which benefited her greatly, so that she was quite comfortable until the winter of 1900, when she had another attack which confined her to her room for three months. She could walk on a level surface, but could not go up or down stairs on account of severe pain in the hips and knees. On sitting down there was cracking of the hip and knee-joints which caused sharp pain and which was distinctly audible to any one in the room. During these attacks there was no fever, and no swelling. In March, 1900, she went to Hot Springs a second time and remained two and a half months. After being there a week or two, she could walk very well and go up or down stairs without suffering pain. During these attacks she always noticed that the pain was much worse immediately after eating. For this reason she was afraid to eat, and often left the table in the middle of a meal on account of the increased severity of the pain.

There is now no pain or swelling in the joints, but her heels are so tender that she walks with difficulty. Her appetite is variable, her bowels regular, and she sleeps well. A physical examination revealed nothing abnormal. The stomach-contents showed free hydrochloric acid 40, total acidity 60. On October 4th, I made a second examination which gave the same result as the first. For a few days in October and for about a week in November she had some pain in her hips, but she was not confined to the house and did not take any medicine for its relief. In January and early in February she had pain in her hips, which was promptly relieved by a few ten-grain doses of salophen. On February 22d, she had another attack of pain in her hips, which the salophen failed to relieve, but which was quickly relieved by methacetine. During October, November and December, this patient had intragastric faradization three times a week. She gained eight pounds in weight during that time and since February has been entirely free from rheumatic pains. On March 18th a third examination of the stomach-contents showed free hydrochloric acid + 32, with a total acidity of 60.

Results of the examinations of the stomach-contents were as follows:

Date.	Günzburg's Test.	Töpfer's Test.	Total Acidity.
Sept. 3, 1900.....	+	40	60
Oct. 1, 1900.....	+	40	60
Mch. 18, 1901.....	+	32	60

The last case I wish to report is one of rheumatoid arthritis.

Case VI.—This patient, Miss W., aged forty years, consulted me March 20, 1900. Her father and only brother were gouty and when nine years of age she had an attack of acute rheumatism. Her joint trouble began when she was twenty-one years of age, and now her left elbow is ankylosed and there is much deformity, especially of the metacarpo-phalangeal articulations of the thumb and first and second fingers of the right hand. She complains of frequent headaches, bloats and belches a great deal, and often induces vomiting to obtain relief. Her appetite is variable, her bowels constipated, and she sleeps badly. An examination of the stomach-contents showed an absence of free hydrochloric acid with a total acidity of 40. Rennet was present. I put her on a diet to suit the condition of the gastric secretions, and for a few weeks she felt much better; she then began to complain of bloating, belching and nausea.

On April 19th I made a second examination of the stomach-contents, at which time free hydrochloric acid was + 40, with a total acidity of 56. I have not seen the patient since I made this examination and do not know the subsequent history of her case.

In regard to the prognosis in chronic rheumatism, Osler[4] states that it is unfavorable, that it is a disease which persists indefinitely, and that the majority of cases resist all methods of treatment. Smith[5] says it is impossible in chronic joint troubles to be certain that simple synovial rheumatism will not *clinically,* in the long run, assume the features of rheumatoid arthritis. In view of these facts it is interesting to notice that the cases just reported recovered from their rheumatism under treatment directed not against the affection of the joints, but under treatment directed against the existing dyspepsia, which in every instance was of nervous origin.

Much has been written on the subject of diet in chronic joint affections, but it is evident that in chronic rheumatism and rheumatoid arthritis a diet should be prescribed, not with a view of suiting the condition of the joints, but in each individual case the diet should be such as best to suit the existing state of the gastric secretions.

THE ADMINISTRATION OF ETHYL CHLORIDE AS A GENERAL ANESTHETIC, WITH DESCRIPTION OF A MASK FOR ITS USE.

BY MARTIN W. WARE, M.D.,
OF NEW YORK;
ATTENDING SURGEON TO THE GOOD SAMARITAN DISPENSARY.

IN an earlier article[1] I set forth in detail the development, history, field and experiences of ethyl chloride, therefore these remarks are intended to cover merely the points of practical importance in its administration.

Accounts of the use of this agent are invariably associated with references to various devices (the masks of Kurschman, Breuer, Schnuneman and Seitz) which had for a common object the economic use of ethyl chloride. Against all of these be it said that they were complicated and by their expense added materially to the cost of the administration of ethyl chloride.

The aim of all was at one and the same time to confine the very volatile vapors of ethyl chloride and yet encompass the essential feature of a due admixture of oxygen, relatively, air. The latter is absolutely essential, since the inhalation of pure ethyl chloride has been proven (Wood and Schleich) to cause death by respiratory paralysis. For this reason a few have seen fit to give ethyl chloride like chloroform on a mask.

This was my starting-point originally, and, while I found it possible to attain narcosis, if thus administered, from the economic standpoint of quantity and cost much was yet to be desired. The main object to accomplish was to shut off all entrance of air from extraneous parts of the mask; to this end I adapted the rubber mouth-piece of the laughing-gas apparatus, since this cone can be applied to the contour of the face,

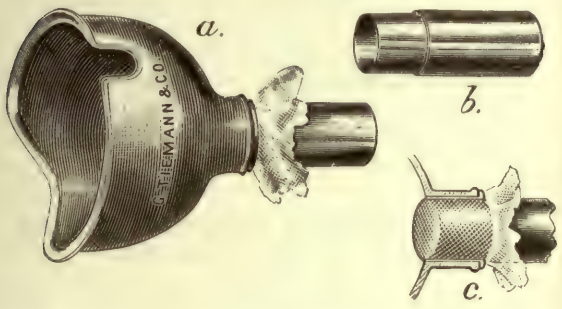
[1] Medical Record, April 6, 1901. "Field for Ethyl Chloride Narcosis."

so as to make an air-tight space about it; this feature, moreover, is common to all masks.

The ethyl chloride passes into the gaseous state so quickly that it ought to be applied at a point very close to the mouth. These main objects I believe to have attained in the mask here pictured and with which I have in 400 instances had 95 per cent. of successes. Of the failures, more hereafter.

The mask is prepared for use by stretching two layers of small-meshed gauze over the end of the tube *b*, which is then held taut by being forced into the neck *c* of the funnel-shaped rubber mouth-piece *a*. The gauze can be renewed at will and the whole apparatus, because of its simplicity, easily rendered sterile, a feature devoutly to be wished for in the laughing-gas mask and other kindred devices. The tube *b* is the channel along which the stream of ethyl chloride is directed against the gauze *c*, intended, not merely to receive the ethyl chloride, but also by impact to break it into still finer particles. At this point the ethyl chloride, evaporating, expands and is held by the walls of the mouth-piece *a* and the sides of the tube *b* which, therefore, act as a chamber to temporarily limit the vapors.

The entrance and exit of air are through one



orifice, so as to minimize the loss of ethyl chloride and merely utilize the quantity momentarily available for one or two respiratory acts. The stream is to be delivered intermittently from tubes provided with an automatic cut-off. The duration of the jet will have to be determined by personal experience. The stream of ethyl chloride issues from the tubes with capillary openings of variable size; therefore, if the stream be fine it escapes slower and the jet has to be sprayed somewhat longer. But it can be more easily controlled from a small opening than a large one, where the escape is so violent as to be wasteful. By an intermittent working of the automatic cut-off an approach to the drop method of chloroformization is attained and I believe this will be found more economical. After a few jets of ethyl chloride have been played on the gauze, a layer of hoar-frost will form, due to the freezing of watery vapor of expired air, but successive respirations again dispel it. This hoar-frost is not objectionable. In fact, with this mask it is a desirable feature, provided ethyl chloride is not given so rapidly as to form a veritable cake of ice, thus cutting off any air and furthermore preventing the liberation of ethyl chloride.

Ethyl chloride is not soluble in water. In the frost, therefore, it is enveloped ready for instant liberation with each respiratory effort. If the frost be too extensive a little remission in the spraying of ethyl chloride will allow it to be dissipated. An approach to this condition is often signaled by a hissing noise during respiration, and when wholly frosted the walls of the mask cave in owing to the suction of inspiration. At this stage the mask should be tilted to permit influx of air and spraying resumed as soon as this phenomena disappears. A trick that will readily dispel the frost consists in sharply blowing into the tube once or twice. It might occur to some that harm may accrue from the inhalation of air cooled in its passage over the frost, but practically this is no factor to be reckoned with. Most decidedly there is a loss by its expansion through the tube during expiration, and, again, there is a most liberal admixture of air during inspiration; yet, administered thus, far less ethyl chloride is efficiently used than in masks of other construction where the chamber for the reception of it is far removed from the mouth and the ethyl chloride administered in a wasteful fashion by spraying on a relatively large quantity at one time. Administered in the latter fashion narcosis can be effected, but we are not in the position to say what quantity of anesthetic actually was responsible for the narcosis. Furthermore, it is dangerous, and therefore wrong, to give the ethyl chloride in a too-concentrated form; finally, this is a wasteful employment of an expensive agent. The ethyl chloride vapor should at the instant of its delivery have free access to the mouth and nose; hence the interposition of a valve, which requires an inspiratory effort to regulate the influx of air, is uncertain and tardy. Likewise, an outlet guarded by a valve for expired air by a route other than the inlet is superfluous, since the latter, being minus a valve, would permit an escape of air by this channel just as readily.

My early trials with the modified laughing-gas mask taught me these points practically, hence the mask pictured is reduced to its simplest form. The rubber mouth-piece, if too large for the features of children, can none the less be adapted by letting the lower end embrace the submental region. For the more fastidious a separate mouth-piece can be had.

Like the other anesthetics, ethyl chloride is seen at its best when administered to children and to young adults, and I therefore counsel those who would acquire a proficiency in its administration to gather their early experience with such subjects. The anesthetic is so fugacious that the tendency of the patient is ever to come out; consequently, we are not likely to err in overdosing and the danger of a cumulative effect is far removed.

The necessity of a pure product is obvious, since many of the products hitherto employed for local anesthesia under the title of ethyl choride are in reality methylated-ethyl chlorides and,

if employed, will fail to be satisfactory if they do not prove dangerous. A pure ethyl chloride is expensive, but less so than laughing-gas, with with which it is henceforth to compete, at least in the hands of the general practitioner. Minor surgery is its field. Relaxation can be obtained always in children and young adults; alcoholics resist unless a preliminary hypodermic injection of morphine be given. Neurotics and highly excited patients, while they may be rendered wholly narcotic, do not become fully relaxed, although sufficiently so for the operation to be performed. Robust individuals make such a demand on the quantity of ethyl chloride that for economic reasons it will not be popular here, though it is possible to render them completely relaxed.

The best conception of the sphere of usefulness of ethyl chloride can be pictured by comparing it with laughing-gas. Rigidity, cyanosis and increased hemorrhage are constant accompaniments of laughing-gas; as for ethyl chloride, while rigidity may exist in a small percentage, cyanosis never occurs. In addition great advantages are its portability and the fact that it requires no expensive apparatus for its administration.

While I have not encountered in 400 applications alarming symptoms in a single instance, I would not have the impression prevail that success will attend every administration. I will put the failures down for the present at 5 per cent. These failures are characterized (1) by a prolonged period of excitation, it being impossible owing to the fugacious character of ethyl chloride to produce the paralytic effect on the cortical centers; (2) although the patient is seemingly narcotic, any painful manipulation causes muscular rigidity as the expression of increased reflex excitability and this interferes with any finer manipulations. In this connection it is opportune to mention that on some occasions it is obvious that the patient presents no signs of being anesthetized other than a blunting of cutaneous sensory perception, yet, on awakening from the dazed condition, the patient will confirm the observation of freedom from any pain during the manipulations. In other instances, while in a like state of preliminary narcosis, neurotics, who, I take it, always constitute the subjects, can be put into a cataleptic condition.

These peculiar phenomena were first observed by dentists who noticed that, after prolonged spraying of ethyl chloride on the gums to affect local anesthesia, patients often became drowsy and extraction was painless. Awakening following instantly after the remission of the ethyl chloride, this condition was not inaptly termed "suggested narcosis," or a state of "soporosis."

My trust in ethyl chloride may be thus summed up: After a use of 400 laughing-gas anesthesias in dispensary practice, I have naught but good to report for it, and if at this hour I have abandoned it for ethyl chloride it is for the following material reasons, which I feel certain must be shared by the general practitioner at large, whose lot it is to do the greater number of minor operations. (1) The primary outlay of a laughing-gas apparatus is tolerably expensive; (2) the cylinders of gas are not provided with a reliable nor suitable device to indicate the contents at any moment, thus necessitating a duplicate cylinder; (3) the cost of gas is rather high, and (4) the whole outfit is very bulky and weighty. Diametrically opposed to this is the ethyl chloride, which is marketable at a lower price than laughing-gas, in vials of 50 c.c., which can be carried about in the pocket; where five operations of a like character may be performed with ethyl chloride, but three can be done with laughing-gas.

In conclusion, I wish to emphasize the fact that this agent is only of service in minor operations and as a preliminary to cut short the agonies of the early stages peculiar to chloroform and ether. The competition that obtains amongst the numerous anesthetics I interpret, not as an index of the inefficiencies of one and all, to be replaced at some future day by a much wrongly hinted at "universal anesthetic," but rather a strife for the finer adjustment of each to its peculiar field. So I venture to predict that the intelligent application of ethyl chloride will prove a useful and grateful agent in minor surgery, at any rate in the hands of the general practitioner, largely supplanting laughing-gas, which might have the foremost place were it not for the deterrent factors thoroughly familiar to us all.

1198 Lexington Avenue.

THE THERAPEUTIC USES OF TRI-CHLOR-TERTIARY-BUTYL-ALCOHOL.[1]

BY E. M. HOUGHTON, PH.C., M.D.,
OF DETROIT;
LECTURER ON EXPERIMENTAL PHARMACOLOGY, DETROIT COLLEGE OF MEDICINE.

NEARLY two years have elapsed since Dr. Aldrich and myself, in a paper published in the *Journal of the American Medical Association* (Sept. 23, 1899), proposed the use of tri-chlor-tertiary-butyl-alcohol as a therapeutic agent. As will appear in subsequent quotations from this paper, which was based on the results of many months of laboratory work and considerable clinical experience, we were careful not to make dogmatic statements relative to its practical value, prefering to point out in a general way its probable field of usefulness and leave the medical profession at large to render the final verdict. I shall endeavor at this time to briefly review the therapeutic literature of the subject and offer some additional suggestions, hoping the subject will elicit free discussion.

Tri-chlor-tertiary-butyl-alcohol, as most of you are aware, is a definite chemical substance of the formula $C\,Cl_3—C(CH_3)_3—OH$ $C_4\,H_7\,O\,Cl_3$. It is a condensation product of chloroform and acetone,

[1] Read before American Therapeutic Society, May, 1901.

occurring as a white, volatile, crystalline substance, possessing a camphoraceous odor and taste. It is very soluble in acetone, alcohol, chloroform, ether, benzine, glacial acetic acid, etc. Less soluble in oils, fats, etc., and sparingly soluble in water, about 1 per cent. at body temperature.

Since this drug belongs to the fatty acid series, we would expect its pharmacologic action to conform in a general way to that of the other members of the group. This supposition is well borne out in many respects by the results obtained in the laboratory and at the bedside. The pharmacologic action of the drug is most pronounced in three directions, viz., as a local anesthetic, antiseptic, and hypnotic, or, if given in extremely large doses, a general anesthetic.

In our first paper we made the following statements: "It is too early to prophesy what position 'the drug' will take in medicine, but the results as a hypnotic and local anesthetic are very encouraging. Culture experiments with various kinds of bacteria also prove that it possesses considerable antiseptic properties," consequently "it may be used independently as a surgical disinfectant." "Possibly the drug will prove to be a useful general anesthetic when administered in large doses; or it may be given before chloroform or ether, and allow complete anesthesia to be produced by the use of a minimum amount of chloroform or ether. Perhaps such administration may prevent the annoying vomiting that so frequently occurs when a patient is being anesthetized."

It has been extremely interesting to follow the clinical reports and compare them with these early suggestions. It will probably be best to discuss the therapeutic uses of the drug under several heads.

Anesthetic Action.—That the drug possesses considerable local anesthetic properties may be demonstrated in various ways in the laboratory. If we infiltrate an animal's ear with a saturated aqueous or normal salt solution of the drug, bits of the ear may be snipped off with shears, without having any symptoms of pain exhibited by the animal. This test is open to objection as normal saline or other indifferent fluids when injected produce a certain amount of pressure anesthesia, still it can be recognized that the degree of anesthesia following the exhibition of the drug is considerably greater than that produced by the saline. Perhaps a better method of showing the local anesthetic action is the following: Inject into the abdominal lymph-sacs of three frogs small quantities of strychnine, just enough to increase the excitability of the spinal cord, so that the slightest external stimulus will bring on a general tetanic spasm. Quickly immerse one of the frogs in the aqueous solution of the drug, partially immerse the second frog in the same solution, and reserve the third as a control. Place the frogs on the table and lightly touch different parts of the body with a feather. The first frog remains quiet no matter where the stimulus be applied, while the third frog when subjected to the same treatment goes off into a tetanic spasm. The second frog, oddly enough, remains quiet when the stimulus is applied to that part of his skin coming in contact with the drug, but has a general tetanic spasm when some other part is stimulated. Indeed, by careful manipulation one can determine to a nicety the line separating the anesthetized and unanesthetized portions of the skin. Application of the drug to the tongue produces a numbing effect similar to but less in degree than cocaine, owing to the difference in the solubility. Considerable care must be exercised in making an aqueous or normal saline solution of the drug on account of its slight solubility in water.

Some writers, especially dentists, have reported the use of saturated 15 per-cent. alcoholic solutions of the drug, but quite a number of cases of sloughing have followed such injections, which may be attributed to the alcohol, since in a series of dogs having their gums injected with 15 per-cent. alcohol, alone, swelling and abscesses have sometimes resulted. As dogs are much less liable to infection than human beings, it seems to be quite likely that adverse results must follow very frequently from the use of such injections, especially when the tissues are of subnormal vitality as is often the case. In special cases, as for the killing and extracting of the nerve from decayed teeth where no harm can result from the destruction of tissue, strong alcoholic, ethereal or other solutions may be employed, but such cases are rare. One may employ almost any quantity of the saturated aqueous or salt solutions without danger of untoward results from the absorption of the drug. For incising a carbuncle boil on the back of a man's neck, I employed something over one ounce of such solution for infiltrating the field of operation.

During the past few years numerous cases of conjunctivitis, due to getting podophyllin, corrosive sublimate, etc., in the eyes have come under my observation. In well-marked cases of this kind the pain is most excruciating. Formerly I relied upon cocaine and cold or hot applications to afford relief; then I commenced using this drug in place of the cocaine and more recently have employed it in combination with the astringent properties of the suprarenal gland with very satisfactory results. Since we have found that dogs do not vomit readily when mustard is given *per os,* if the drug is administered previously, we suggested that the nausea and vomiting occurring at the same time or following the use of chloroform or ether might be prevented or greatly lessened by its administration. Hirshman and Stone, acting on this suggestion, have each reported a series of cases in which it was employed before operation with much satisfaction.

Numerous cases of chronic alcoholism have been reported in which the drug was employed, usually with success, to allay the gastric irritation in order to allow the patient to retain nour-

ishment. A few cases of gastric carcinoma accompanied with pain and vomiting have been relieved. However, in some cases it has not been of benefit, possibly because the drug did not penetrate the diseased tissue. Seemingly the drug has been of value in checking the vomiting of pregnancy and seasickness. I am inclined to believe that the benefit obtained from the drug in these and other cases of gastric irritation is due in part to the local anesthesia action and in part to depression of the central nervous system. This view is borne out by the fact that less chloroform and ether are required to produce anesthesia when the drug is previously administered. Observations of a few cases of gastro-intestinal irritation, due to bacterial activity, especially in small children, lead me to believe it may be of some service, on account of its antiseptic properties.

Antiseptic Action.—Since organic fluids, as preparations of the suprarenal gland, undergo putrefaction, and cultures of bacteria are killed by the drug, while ciliated epithelia and spermatozoa remain active for hours, when bathed with saturated aqueous solution, it was decided to test its value as an antiseptic in place of iodoform, etc., as a surgical dressing, believing that it would be an advantage to have the combined action of a local anesthetic and an antiseptic for most surgical purposes, and especially as the drug when absorbed lessens the nervous excitability. Numerous reports indicate that these expectations were justified, especially have good results been obtained in minor surgery. Dewar reports a case of extensive laceration of the arm, a cog-wheel injury, where the local anesthesia action from the application of saturated aqueous solution of the drug sufficed to allow the placing of thirty sutures without pain. Crystals of the drug were then sprinkled over the injured member, and gauze prepared from the same applied; contrary to expectation no further pain was experienced and the wounds healed by first intention without sloughing.

Moore reports a similar case: Woman attacked by a bull-dog. Several lacerations of leg extending from knee to ankle. Some of the muscles had been severed and torn from their positions and shreds of tissue were hanging from the wounds. The patient was suffering from shock and refused to take an anesthetic. "The wounds were cleansed with hot 1-1,000 bichloride. A hot saturated solution of the drug (tri-chlor-tertiary-butyl-alcohol) was applied, five minutes later the wounds were closed with eighteen sutures; wherever there had been a thorough application of the solution not a particle of pain was experienced from the passage of the needle." The wounds healed completely without suppuration.

Siter, in concluding a recent paper reporting a series of 32 cases representing a great variety of surgical conditions, makes the following statement:

"The use of 'the drug' in dusting powders for painful granulation wounds has been wonderfully successful as far as analgesia is concerned. It does not seem to delay union nor granulation. and it can be used in combination with almost any dusting powder. In the cases outlined below it was used with boric acid. It cannot be said, however, to hasten granulation, and, as far as I have observed, all it does is to mitigate or entirely allay pain in the majority of cases. This, after all, is a good deal gained for the patient and the physician. The drug, I think, has a great future, at least in minor surgery, as an analgesic dressing. I cannot see why it should not be successful in major surgery when it may be prudent at all to use a dusting powder."

I have employed the drug in a large number of accident cases to allay the pain produced by the injury and subsequent treatment, and as an antiseptic dressing in most cases to the satisfaction of the patient and myself. Nearly always after the injured member has been plunged in the aqueous solution of the drug for a few moments, the patient has remarked: "It don't hurt any more." In a few cases where the injury has been mainly due to bruising of the parts, rather than to incision or laceration, since a solution of this drug like other drugs does not readily penetrate the skin, no effect was apparent. As an antiseptic dressing, it has proved fully as efficient, whether applied in powder or upon gauze, as iodoform, and without complaints of the disagreeable odor that so generally prevail when the latter is employed. In a few cases where the injury has been extensive, and the chance of absorption proportionately great, the patients have stated of their own accord that they felt very sleepy, and one complained of dizziness, probably from the central action of the drug absorbed. Numerous cases of burns have come under my observation, likewise several cases have been reported, where the drug was applied in combination with an oil or fat with good results. Perhaps lanolin has been the best vehicle for this purpose, as it penetrates the skin more readily than the others.

At my suggestion several army surgeons are testing the merits of the drug as a surgical dressing in the field. It may prove to be of much service as a "first aid" antiseptic when put up in easily-opened, tightly-sealed containers to prevent volatilization. As there is no danger of toxic results from absorption even when the crystals are employed, wound asepsis is promoted by its antiseptic action, pain lessened by its local anesthetic properties, and the central nervous system is quieted by its hypnotic influence after absorption.

In cases where a stronger degree of local anesthesia is desired than is produced by a saturated aqueous solution, cocaine may be added in any amount desired. Indeed, on account of the antiseptic action of the drug, cocaine solutions may be rendered sterile and kept on hand always ready for instant use. One case of successful spinal anesthesia produced by the drug has been reported; however, since several unsuccessful attempts have been called to my attention, and,

moreover, since I have not been able to obtain positive results in the laboratory, I am inclined to doubt its efficiency for this purpose. The combined fluid has been employed by several surgeons with entire satisfaction. In a series of experiments I am conducting at present, animals receiving considerably more than a fatal dose of cocaine can be saved by injecting at the same time a saturated normal saline solution of the drug. This might be expected since cocaine, when absorbed, *stimulates* the central nervous system, while the other *depresses*.

In solution or combined with oils, vaseline, cacao-butter, etc., the drug has been applied with more or less success to the rectum and genito-urinary tract as an obtundent or antiseptic, or both. It seems to me quite probable that it may prove to be of considerable value in various conditions affecting these parts and especially as a douche in cystitis and various gynecological affections, not only on account of its local anesthesia and antiseptic properties, but because it does not coagulate albumins, thus allowing permeation of the tissues, nor harm animal cells.

As a Hypnotic.—Before discussing the hypnotic action of the drug, I desire to quote from a paper which was read before the American Physiological Society (Dec. 29, 1899), by Dr. Aldrich and myself, and which gives a brief summary of the more important effects produced by the drug after absorption. "If crystals of the drug be administered to animals *per os* or *per rectum*, if a solution be given *per os, per rectum*, subcutaneously, intravenously, intra-abdominally, or if the animal be confined in a tight box and compelled to inhale air saturated with its vapors, all degrees of hypnosis to complete anesthesia are produced, lasting from a few hours to several days depending on the amount of the substance entering the system, the animal finally recovering in excellent condition if the dose be not too large. However, when an extremely large quantity of the drug is administered, the animal remains completely insensible for several days, the respiration becomes slower and weaker, finally ceasing altogether, the heart, however, continuing to beat for some time after.

"The drug is quickly absorbed from the alimentary tract, especially when in solution, and can readily be obtained from the blood in crystalline form. The spectroscope fails to show any effect of the drug as hemoglobin in the test-tube or in the animal body. The pulse-rate is slightly lessened, but the action of the heart under the influence of the drug remains excellent until the organism begins to suffer from a lack of oxygen. Frogs are very quickly overcome by the action of the drug when it is applied externally, in vapor or liquid form. The local application of aqueous solutions of the drug to the laid-bare frog's heart produces slowing of the rate and a more complete contraction of the organ—reminding one of a digitalis heart.

"Kymographic tracings, taken from the carotid artery of dogs, show that the blood-pressure usually remains unaffected, in several instances the pressure being a little higher at the end of an experiment occupying six hours than at the beginning. The amplitude of the contractions of the ventricle as recorded by the myocardiograph likewise remains unchanged for many hours. Quite large quantities of the drug can be obtained from the brain substance after as much of the blood is removed as possible, by allowing normal saline solution to flow under pressure through the carotid artery and out of the jugular vein.

"We would naturally expect, since the drug is volatile even at ordinary temperatures, and since it circulates in the blood, that it would be eliminated by the lungs. Carefully conducted experiments thus far have failed, however, to detect it in the expired air. In any case, it must be eliminated in very small quantity. The chlorides in the urine of a dog fed on a fixed diet are markedly increased after the administration of the drug. . . . If the administration is kept up for some weeks, small amounts of the drug also appear in the urine. It seems probable that the drug is decomposed or burned down in the body. This view would accord best with the facts we have already observed."

From these statements it will appear that the drug after absorption produces results similar to those which follow the internal administration of the other chlorine derivatives of the alcohol series. However, in some respects, it differs very materially from its relatives. The action is more prolonged, it almost never produces gastric disturbances, and does not depress the circulatory system to the same extent as many of them do.

Rudolf has contended that since the drug produces considerable lowering of temperature in animals, when administered in doses several times larger than are recommended for therapeutic purposes, harmful results are likely to occur. In his experiments the temperature of the room was kept at 55° to 65° F., which produces a greater fall than would have otherwise occurred. Artificial heat prevents too great fall of temperature, the same as with chloral. Indian cannabis is one of the lest harmful of drugs, since, from an extensive search of the literature, I am unable to find a fatal case of acute poisoning recorded. Often in animals I have found the rectal temperature 10° to 12° below normal after giving Indian cannabis, yet the animals would make an excellent recovery in a very short time.

Donald, in describing a case where an overdose of the drug had been taken, says in conclusion: "That the drug is a hypnotic, five or six days' sleep from the administration of the drug will testify; that it is a safe hypnotic this period of sleep from the use of 120 grains of the drug, with no bad nor untoward effects, should be ample evidence."

West, in reporting another case, says: "I discovered that not less than 165 grains of the drug had been given to the patient between the hours

of 3.30 p. m. and 5.00 a. m., a period of thirteen and one-half hours. His pulse, however, was strong and regular, and running about 90 a minute. The respirations were deep, regular, and slightly accelerated, but never above 22. On the third day thereafter the pulse-rate rose to 100, which I believe was due to deficient nourishment. The principal effect of the drug was complete, general anesthesia, which lasted for one day, after which it gradually abated, the patient being restored to his normal condition on the fourth day. My only treatment consisted of hypodermatic injections of strychnine sulphate in $^1/_{25}$-grain doses."

These cases certainly refute Rudolf's contention and show that the exhibition of the drug in hypnotic doses is practically devoid of danger and indicate the possibility of employing it as a general anesthetic, but such a step should not be taken until after much more extended laboratory and clinical observations have been made; methods of feeding and nursing must be devised, and even then, since the anesthesia is so prolonged, we should hesitate about employing it. A number of physicians reported an entire absence of hypnotic action where the drug has been prescribed in 10- to 20-grain doses, to relieve extreme pain, but all of the members of the fatty acid series are open to the same objection. In these cases we still have to rely upon morphine. Hare, Stevens, and others generally have found it an efficacious hypnotic in chronic Bright's disease, with or without accompanying cardiac complications, except in those cases where precordial pain was a prominent symptom. In tuberculosis, it has frequently been found valuable, but sometimes fails to produce the desired results, likewise in typhoid fever the testimony is variable. It has been suggested as a useful remedy in asthma and whooping-cough, and several cases have been treated with benefit. Epileptic attacks are sometimes lessened in frequency and severity; whether the effect is palliative or curative remains to be seen.

Baumeister has described a case of traumatic tetanus which he satisfactorily treated with the drug. It would seem that the prolonged action of the drug would render it the most valuable remedy in the alcohol series for this disease.

Wade has reported 18 cases in which he has employed the drug as a chemical restraint for the insane, giving it in 15- to 60-grain doses, an average of 35 grains, and summarizes his results as follows: "It is most valuable and serviceable in the motor excitement of acute maniacal attacks of agitated melancholia. It could very probably be used with benefit in the motor excitement of general paresis. The fact that it does not depress the heart action ensures for the drug special consideration in all cases of acute insanity with restlessness where it is necessary to preserve all the vital forces to tide the patient over the attack and prevent death from exhaustion. It is more agreeable to take than paraldehyde and does not leave bad after-effects.

From several letters and oral reports I have received, from physicians employing the drug in insane asylums, it would appear that it cannot be employed with entire safety in the motor excitement of general paresis. However, it may be that this is one of the limitations of the drug, but the number of cases reported is too small to draw positive conclusions, although the other types of insanity with motor excitement appear generally to be benefited.

Stone has just reported having employed the drug as an ante-operative hypnotic in doses of 5 to 20 grains in 4 cases with a great lessening of unsatisfactory after-results; in 5 cases he gave the drug internally, before producing spinal anesthesia with a solution containing 1 per cent. cocaine and .8 per cent. of the drug. He contrasts the results in these five cases with 200 previous cases of spinal anesthesia in which he did not use it, and claims that the post-operative symptoms were much less pronounced than usual. Since animals can be readily anesthetized by inhalation of vapors of the drug, it seems to me quite probable that by means of a suitable inhaler it might be advantageously applied as a hypnotic in this way.

Most observers comment on the lack of after-effects following the internal use of the drug. Occasionally where it has been taken late at night some dulness and, in a few cases, dizziness have been observed. Many specific cases might be cited and other suggestions offered, but this paper is already longer than I intended, and I will refer those especially interested in the subject to the bibliography attached, which I have endeavored to bring up to date.

From what has already been said relative to the therapeutic uses of this drug, I believe that we are warranted in drawing the conclusion that, owing to its moderate antiseptic, local anesthetic and hypnotic properties, its apparent harmlessness to animal tissues when brought into direct contact with them by local application or when absorbed and distributed to various parts of the body by the circulatory system, it bids fair to demonstrate for itself a wide field of usefulness. Our experience, both laboratory and clinical, is too limited to warrant our drawing too positive conclusions relative to its limitations for clinical purposes. One of the most important points to be determined is the question of dosage. Like all other drugs used in medicine, its therapeutic limitations must be worked out.

Mastitis.—The Sloane Maternity Hospital treatment for mastitis is to put the patient to bed on a dry diet, give a dose of magnesium sulphate which is considered better than Rochelle salts, and stop the baby's nursing. An ice-bag is applied, and the breasts are massaged, and then emptied with a breast-pump every two hours. The bowels must be kept freely open.

BELLADONNA VS. SCOPOLIA.

BY REYNOLD WEBB WILCOX, M.D., LL.D.,
OF NEW YORK;
PROFESSOR OF MEDICINE AND THERAPEUTICS AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; PHYSICIAN TO ST. MARK'S HOSPITAL.

IN a recent paper on this subject[1] I reached the conclusion that scopolia rhizome as fluid-extract incorporated into a liniment is devoid of therapeutic action and should not be substituted for belladonna root; on the contrary, belladonna root under similar conditions produced rise of temperature, pulse and respiratory rate, difficult respiration, flushing of the face, reddened mucosæ, dry tongue and thirst, headache, drowsiness and dilatation of pupils—these symptoms becoming more marked as the amount of the liniment was increased and left no doubt as to the activity of the preparation.

In order to determine if the camphor in the liniment interfered with the production of symptoms from the use of scopolia liniment, a new series of observations was commenced which is the basis of this report.

The same method of procedure was adopted as was employed for the first series of experiments. A quantity of the fluid-extract (noted in each experiment) was taken and, after the temperature, pulse and respiration had been recorded, this was rubbed into the inner surface of the forearm until the skin became again dry. Records were made at the end of sixty minutes unless otherwise specified, the first being made immediately before using. Both the belladonna and scopolia fluid-extracts were made up to the assayed strength of .55 per cent. total alkaloids.

The observations were as follows:

FLUID-EXTRACT "A."

No.	Amount.	T.	P.	R.
1.	30 minims	98.8°	84	20
		99.2°	88	20
2.	30 "	98.8°	76	22
		100°	88	24
3.	30 "	99.2°	96	22

The net result is as follows:

	T.	P.	R.
"A."	+2.4°	+32	+4
"B."	+1.2°	+ 5	+10

Evidently "A" influenced temperature and pulse rate more than "B" while the latter increased the rate of respiration. Fluid-extract "A" was evidently made from belladonna root.

The results obtained show that, while the camphor did not interfere with the results so far as the scopolia rhizome fluid-extract was concerned, it certainly aided in the absorption of the active principles of belladonna root. This second series of experiments gives practically the same results as the first and the conclusion so far as concerns scopolia still obtains. Knowing that the effects of liniments and other external applications are considerably greater if vigorous friction on rubbing is employed, in all these observations this was insisted upon.

"The ratio of absorption with the use of an occlusive dressing," as Hallberg, in noticing my former paper, very properly suggests, "would be interesting," and to determine this experiments have been undertaken and carried out for several months. These will be reported at a later date and their results will, I trust, be of considerable importance in solving the debatable questions in regard to the efficacy of plasters. So far as this method of application—thorough inunctions—is concerned scopolia rhizome cannot be substituted for belladonna-root.

ULCER OF THE DUODENUM CONSIDERED FROM A SURGICAL STANDPOINT.[1]

BY D. S. FAIRCHILD, M.D.,
OF CLINTON, IOWA;
PROFESSOR OF SURGICAL PATHOLOGY, DRAKE UNIVERSITY.

THE treatment of ulcer of the duodenum will no doubt be considered from the standpoint of medicine alone for many years to come, except when perforation has taken place. Nevertheless the good results which have followed operations for ulcer of the stomach in certain cases encourage the belief that surgical means may be extended to like conditions in the duodenum.

In January of this year (1901), I was led to open the abdomen on the supposition that I had a case of intestinal obstruction to deal with, but discovered three perforations in the duodenum which had given rise to a peritonitis. The perforations were sutured, the abdomen thoroughly irrigated and closed with drainage. The patient died four hours later. The history of the case had been very misleading. I saw the patient in consultation the night previous to the operation and learned that she had been ill three weeks with apparently increasing obstruction of the colon near the sigmoid. The woman was fifty years old and had been in poor health for several years. At the time I saw her, the transverse and descending colon were greatly distended with gas which gave her great distress. Suspecting a

[1] Read before the Iowa State Medical Society, May 15, 16, 17, 1901.

malignant growth compressing the sigmoid, it was hoped that an iliac colostomy might afford temporary relief. Not being sure of my diagnosis, an incision was made in the left side, with the line of the umbilicus as a center—realizing that the usual incision for colostomy would not permit of a satisfactory exploration of the abdomen. Going upward I soon found intestinal contents slowly escaping from under the transverse colon. The incision was extended upward, the distended colon gently displaced and underneath escaping from three openings in the duodenum intestinal contents were seen. It at once became apparent that the perforations had at first been covered by the transverse colon and some adhesions had formed to protect the peritoneal cavity, but they had become inadequate for the purpose and a leakage had occurred attended by an extension of the peritonitis along the course of the colon with paralysis of the bowel.

The literature covering the surgical treatment of ulcer of the duodenum is very limited. Dr. Robert F. Weir of New York in his Presidential Address before the American Surgical Association was able to find 51 operated cases reported. These were all for duodenum perforations.

Several gastro-enterostomies have, however, been reported for symptoms of pyloric obstruction which on operation were found to be due to contraction of the duodenum from presumably healed or partially healed ulcers.

The difficulty in correctly diagnosing a duodenal ulcer is illustrated by the fact that of the 51 reported cases of perforation treated by operation the diagnosis was wrong 38 times, while only 13 were correctly or approximately correctly diagnosed. In 26 cases the ulcer was not found at the time of the operation, but afterward at the postmortem. The mistake was mostly made of diagnosing the cases as appendicitis, 18 times, acute peritonitis, 13 times, or intestinal obstruction, 5 times, as in my own case. The diagnosis based on the symptoms at the time of perforation is extremely difficult, or nearly impossible, but when the history of the case is taken into consideration much light is thrown upon it. In the great majority of cases the existence of gastric or dyspeptic symptoms will be found, but in a considerable number of the class of patients in which duodenum ulcers occur, the history will be obscure on account of failure to make close observations and of the lack of ability of the patient to describe with clearness the past symptoms. This was particularly true in my own case. It was only possible to ascertain that digestive troubles had existed for some time, and that some three weeks before the operation sharp pain had been felt in the epigastric and hypochondriac regions, with constipation and some abdominal distention. The physician who was called was not able to determine anything definite at the time. The patient had led a hard life and had lived on coarse food, which in the nature of things would suggest some indefinite stomach and intestinal trouble attended with a certain degree of auto-intoxication. The leakage had set up an adhesive inflammation which weakly united the transverse colon over the perforations, which for a time shut off the general peritoneal cavity from infection by intestinal contents. The infection later extended along the intestines toward the sigmoid, resulting in a paralysis of the bowel with distention, giving the deceptive indication of a sigmoid obstruction.

The previous history of a patient when perforation has taken place will be of considerable value in determining the probable point of escape of infectious matters when symptoms of such an accident occur. Previous to 1895 only 2 out of 20 cases were correctly diagnosed; since that time, of the 31 cases of Weir's tables, 11 were correctly diagnosed, or 2 per cent. of the first series and 35 per cent. of the seconr series, showing the greater alertness of surgeons, and the greater experience from the consideration of gastric ulcers.

In non-perforating ulcers of the duodenum the symptoms are rarely clear enough to make a positive diagnosis. The confusing influence of gall-bladder affections, gastric ulcer and adhesions about the pylorus may lead to an error in diagnosis which may only be positively cleared up after making an exploratory invision. There are, however, certain symptoms which if always present and occurring in certain relative order would make the diagnosis comparatively easy, such as the pain in the right hypochondrium which comes on two to four hours after meals, unrelieved by vomiting and bloody stools. In gastric ulcer the symptoms in relation to pain are nearly reversed, as pain immediately after meals is relieved by vomiting. There is frequently bloody vomiting and rarely bloody stools.

If a diagnosis of duodenal ulcer can be made in a non-perforating case an operation seems to be indicated, before grave and alarming symptoms develop. The location of the ulcer is such that efforts at healing are rarely attended with success and if healing does take place a contraction of tissue is probable thus leading to symptoms of stenosis. If the symptoms of ulcer are sufficiently positive and persistent to warrant a diagnosis the same indications for surgical treatment exist as for ulcer of the stomach.

The only operation for non-perforating ulcer of the duodenum is a gastro-enterostomy. As yet but little has been done in a surgical direction for these patients. The two gastro-enterostomies done by Codevilla, with recovery in both cases, illustrate what may be accomplished. The intractable cases of gastric ulcer which continue to be treated by medical means are now, in numerous instances, cured by a gastro-enterostomy with so small a percentage of mortality as not to militate seriously against the procedure. In fact, the results have been so gratifying that one familiar with them would be little inclined to advise against the operation in the cases which do not, with reasonable permanency, repond to other treatment. The same logic should apply to duodenal ulcers.

In regard to perforating ulcers of the duodenum, it may be said that in a certain percentage no very marked symptoms existed prior to perforation. In 20 out of 25 of Schwartz's cases the patients were in apparently good health. In only 5 were there previous stomach symptoms. In Dr. Weir's collection, 25 out of 34 had gastric symptoms previous to perforation. In the cases collected by different writers a considerable variation appears as to the percentage showing symptoms of diagnostic value previous to perforation taking place. Hence the most watchful care on the part of the surgeon will not prevent the affection being overlooked, as a rule, until symptoms of perforation have appeared. In other words, the operation will be done in but few cases until perforation has taken place.

In chronic cases of duodenal obstruction due to healed or partially healed ulcers, the differential diagnosis of duodenal and pyloric obstruction from similar causes will be made prior to operation in only a few cases. While it may be contended that duodenal ulcers should be treated on the same general plan as gastric ulcers, when the diagnosis can be made, operation will be generally called for in perforation cases only.

The importance of early operation in duodenal ulcers is very great. If the abdomen is not opened within twenty-four hours but little can be expected. In certain patients, if the perforation is very small, adhesions may form which temporarily protect the general peritoneal cavity. Such occurred in my case, in Case XXIV. of Weir's tables, and in the case reported by Landerer and Glückmann in which the duodenum, stomach and colon were sutured together. In this latter the patient survived eight months and died from operation for suppurative peritonitis. Autopsy showed a new perforation in the posterior wall. In case XXI. reported by Lennander, nine days after a sudden attack of pain, vomiting occurred followed by bloody stools. An abdominal incision was made and on separating the abdominal walls from the viscera several small abscesses were found. A perforation was discovered and sutured. Five weeks later the patient died from pulmonary thrombosis. At autopsy two other unhealed ulcers were found, not perforated. Case XLIV., reported by Wright and Burry, developed a fluctuating tumor in region of gall-bladder which increased to considerable size. A diagnosis of hydronephrosis was made. On incision a discharge of a quart of clear fluid was evacuated. Next day the gauze was saturated with a sour fluid. The third day food was noticed on the dressing. Patient died on the fifth day from acute bronchitis. Postmortem showed duodenal perforation.

Of the 51 cases of operation for duodenum ulcer given in the tables referred to in Weir's paper, 6 made permanent recovery. One died eight months after first operation for a second perforation. One died in two months from obstruction in the ilium. At the operation it was found that a perforation existed just above the obstruction.

MEDICAL PROGRESS.

Sudden Suppresssion in the Treatment of Opium Habit.—BRUNET (*Le Progrès Méd.* June 22, 1901) advocates sudden suppression in the treatment of the opium habit. A prerequisite to treatment is the removal from the patient's surroundings of all paraphernalia suggestive of his former habit. A reliable person must be in charge of the patient and the physician should be near at hand during the critical period. The least possible medication favors the detoxication of the system. For insomnia bromide and chloral are permissible at night. Doses of one grain of extract of cannabis indica may be given unknown to the patient once a day as long as cerebral depression continues, and for otherwise uncontrollable pain morphine injections may occasionally be given but never with the patient's knowledge. To sustain a weak heart during the critical period caffeine may be used. Subsequently the case can be managed by fresh air, tonics, massage, baths, and an occasional small dose of trional or sulfonal. A complete change of surroundings for two or three months is desirable.

Surgery in Spina Bifida.—L. MARSHALL (*Brit. Med. Jour.*, June 22, 1901) states that there is one very important point to be observed in the surgical treatment of spina bifida, which is apt to be overlooked by the majority of operators. This is the retention of the cerebrospinal fluid within the cranial and vertebral cavities. During an experience dating back fully two years and covering a number of successful cases, he has found this end to be fully and conveniently subserved by elevating the lower extremities and hips and depressing the head and upper part of the trunk, both during the operation and during the after-treatment. By a careful maintenance of this semi-inverted posture for a period varying between one and two weeks all danger of accidental outflow of this all-important water-bed of the nervous substance is avoided. The further technic consists in making a very small incision into the sac and cautiously evacuating its fluid contents. Then the incision is enlarged to expose the true membranous sac which is next dissected free of the wall as far as the spine, cut away if redundant, and then folded inward upon itself in a pad-like form and sutured by Lembert stitches precisely like the bowel. The skin is then reduced to a suitable size for the flap and sutured over this membranous inner pad with interrupted silkwormgut stitches. The outer dressing consists of cyanide gauze laid down in many layers and fastened with collodion.

Inoculation for the Prevention of Typhoid Fever.—In a typhoid epidemic at Richmond, Asylum CULLINAN (*Dublin Jour. Med. Sc.*, July, 1901) practised serum inoculation on a large number of persons exposed to infection, using in each case ¾ c.c. of serum prepared by Professor Wright of Netley. None of the nurses in the asylum were inoculated, and in proportion to their

numbers the nurses suffered much more severely than the patients. Cullinan believes that inoculation is potent to confer immunity against typhoid, while admitting the failure of the measure among the soldiers in South Africa. The constitutional disturbance following inoculation did not prove severe in any case among the inmates of Richmond Asylum.

Epigastric Pain.—Inflammatory distention of the gall-bladder often leads to severe, cramping pains, variously attributed to gastralgia, cardialgia, gastrodynia and gastrospasm. H. W. BETTMANN (*Cleveland Jour. of Med..*, July, 1901) follows the rule to suspect gall-stones when a paroxysmal, severe epigastric pain recurs regularly several hours after eating, if a careful examination of the secretions and digestive functions of the stomach reveals no abnormality, and tabes does not exist. An interesting form of epigastric pain occurs in chlorotic girls. It is of a gnawing or boring character, increased by ingestion of food, and suggesting gastric ulcer. There is no nausea nor vomiting, and the pain is always in the middle line. A form of epigastric pain accompanies arteriosclerosis. It is a crampy feeling coming on after meals when any exercise has been indulged in. The pain may stop when the patient remains quiet. It occurs only in elderly people.

Hydro-Electric Baths in Pulmonary Tuberculosis.—Following the use of insufflations and inhalations of iodine, formaldehyde and menthol, MAGGIORANI (*Le Progrès Méd.*, June 29, 1901) treated 500 cases of pulmonary tuberculosis by means of hydro-electric baths, given every other day. Lukewarm water was used and each bath lasted ten or twelve minutes. The following results were noted: Increase of body weight, digestive power, hemoglobin, acidity and specific gravity of urine; diminution of cardiac frequency, respirations, pain, night-sweats, rheumatoid attacks; amelioration of genital asthenia; abolition of insomnia; regulation of intestinal function and of menstruation; strengthening of the heart.

Three Symptoms from Abnormal Conditions of the Foot.—H. W. FREIBERG (*Cleveland Jour. of Med.*, July, 1901) concludes that abnormal conditions of the foot may be the cause of pains in the knee, with or without themselves presenting subjective symptoms. Pronated and flatfoot is the most frequent cause, possibly from shortening of the calf-muscles, and their drawing on the capsule of the knee through the medium of the plantaris. Pal considers flatfoot also a cause of *meralgia paræsthetica.*

Mean Arterial Pressure in Insanity.—Observations by W. R. DAWSON (*Dublin Jour. Med. Sc.*, July, 1901) support the view that states of mental depression and stupor are associated with high arterial tension; states of mental exaltation and excitement, with low arterial tension. These facts afford a somewhat empirical basis for treatment. Melancholic cases beginning with high tension show a gradual decline of tension in proportion to the mental improvement.

Tuberculous Meningitis with Hemiplegia.—In a case reported by SOUQUÉS and QUISERNE (*La Méd. Moderne*, June, 26, 1901) tuberculous meningitis manifested itself at first by transient attacks of hemiplegia lasting for several minutes or even for one or two hours. After four days the hemiplegia became permanent. Kernig's sign being present, lumbar puncture was resorted to and the diagnosis confirmed. In the absence of cyto-diagnosis by means of lumbar puncture the question of a possible cerebral tumor would have remained.

The Reaction of Fixation with Sterilized Typhoid Cultures.—The reaction of fixation in the diagnosis of typhoid has been obtained by WIDAL and LE SOURD (*La Presse Méd.*, June 26, 1901) by means of a sterilized culture of typhoid bacilli, the latter being substituted for the living germs heretofore used. A gelatin culture is used and from this an emulsion is prepared in a .7 per cent. (seven-tenths per cent.) solution of sodium chloride. The emulsion is exposed to a temperature of 61° C. for three-quarters of an hour.

Epithelioma of the Penis.—The most frequent form of carcinoma of the penis is epithelioma. PATTERSON (*Univ. of Penn. Med. Bull.*, July, 1901) considers phimosis a strong predisposing factor. The virus of syphilis has nothing to do with epithelioma, but the scar of an old syphilitic lesion constitutes an area of decreased resistance. The question of contagiousness of epithelioma is regarded as still to be decided. Origin in the urethra is relatively rare; a more common place of origin is the glans or prepuce. The only safe treatment in any stage consists in the thorough eradication of the area of disease and of all involved lymphatic glands.

Primary Cystorrhaphy After Suprapubic Cystotomy.—DR. BALACESCER (*Centralbl. f. Chir.* 1901, No. 25) states that in the clinic of T. Jonnesco at Bucharest the following method has been successfully and repeatedly performed on dogs and then on man of making a primary cystorrhaphy after incising the bladder. For the first eight days a retention catheter is carried, after that the patient voids his own urine or is regularly catheterized. In a few patients no retention-catheter was used and either voluntary micturition or catheterism was performed. The bladder is freely exposed through the usual suprapubic vertical straight incision, and its upper and lateral walls freed of peritoneum with the finger in order to permit of its being more readily and prominently brought up into the wound. When so presenting it is incised layer-by-layer and the stone removed. As a rule the bladder should be empty at the time of the operation, and always when possible a preliminary irrigation performed for about one week. When the bladder is ready for closing for the length of the wound on one side only the mucous membrane is carefully dissected free over a width of about one centimeter. The mucous membrane is now brought together very carefully so that each extremity is closed. Then the muscular layers

are united so that the last stitches are beyond and shut off the wound ends. Then over the entire suture line the muscle walls are apposed by Lembert sutures, exactly as in the intestine. Such a procedure is absolutely safe and renders it possible to get the patient up in twelve days.

Adenoma Sebaceum of the Non-Symmetrical Type.—Two main types of sebaceous adenomata are distinguished by GOTTHEIL (*Jour. Am. Med. Assoc.*, July 20, 1901). The first accords with Unna's definition: Benign, irregular outgrowths of the sebaceous epithelium going on to fatty but not to colloid metamorphosis. The second is a simple hypertrophy of apparently normal sebaceous-gland tissue. Clinically, most cases are multiple, yellowish, firm nodules without central depression, commonly situated on the nose or nasolabial folds. A case observed by the author presented a growth on the right parietal scalp, forming a curved, elongated pinkish-yellow patch 2½ inches long by ¾ inch broad. Normal scalp was entirely absent over this area; a few lanugo hairs were present. Prior to microscopical examination the case was regarded as xanthoma. The diseased area was excised.

Total Extirpation of Thyroid.—Acute dyspneic symptoms in a boy of sixteen were treated by tracheotomy without relief in a case reported by COTT (*Jour. Amer. Med. Assoc.*, July 20, 1901). Removal of the thyroid was then attempted under eucain and completed under chloroform. The gland weighed 5½ ounces. In eleven months after the operation the boy gained thirty pounds and grew three inches.

Venom and Antivenene.—As the result of experimental research along these lines, J. MCFARLAND (*Proc. of Phila. Path. Soc.*, June, 1901) concludes as follows: (1) By subcutaneous and intravenous injection of unheated crotalus venom it is possible to immunize horses to the chief toxic element; (2) the immunity thus afforded is very slightly protective against the initaline poison contained in the venom and animals whose serum contains much antivenene may succumb to its local effects; (3) the development of the immunity is accompanied by the occurrence of large quantities of antivenene in the blood of these animals; (4) the antivenene is fully able to save animals from both crotalus and cobra venoms: (5) the quantity of antivenene in the blood fluctuates according to circumstances as do the other antitoxic sera declining as the vital condition of the horse is depressed; (6) the normal endurance of horses to venom varies considerably, as does their resistance to diphtheria and tetanus, so that only one out of three horses survived treatment for a considerable length of time; (7) the intravenous method of administering the unmodified venoms is by far the best and is not attended by sloughing of the tissues. Great care must, however, be exercised in order that the venom does not enter the subcutaneous tissues; (8) as the immunity does not extend to the initaline poison and as the protection afforded to animals receiving antivenene is against the venoms only, it is probable that Calmette's method of immunizing animals with modified (heated) venom which contains none of the initaline substance is greatly to be preferred as causing the animals less suffering and not endangering their lives.

Plague Inoculation.—In regard to the efficiency of prophylactic inoculation with Haffkine's vaccine in plague, W. B. BANNERMANN (*Ctbl. f. Bäk.*, June 24, 1901) says that such inoculations have been carried out by the Government on a large scale in many parts of India. In 6,000 cases the mortality was 43.5 per cent. in the inoculated and 73.7 per cent. in the uninoculated. These results are at variance with those obtained by Calmette in his laboratory observations, who claims that inoculation with this virus aggravates the disease and greatly increases the mortality. It may be said that inoculation with this vaccine begins to show its beneficial effects in a shorter time than any preventative treatment known, being apparent in less than twenty-four hours. The length of time the protection lasts is still undecided, but evidence is accumulating in India to show that a good effect is still visible as long as eighteen months subsequent to the operation.

Natural and Artificial Immunity.—After a series of experimental studies on this subject A. WASSERMANN (*Ztschrift. für Hygiene und Inf.*, June, 1901) draws the following conclusions: (1) The accessory factors are intravital present substances; (2) these factors play a causative part in all known varieties of natural immunity; (3) they are not the only cause of natural immunity; (4) in certain species of hereditary immunity no causative part can be assigned to these factors; (5) in the typhoid infection of guinea-pigs these factors have a direct influence upon the acute, subacute or chronic course of the disease; (6) the action of specific immunizing sera in the body depends upon the combination of these factors with the immunizing bodies of Pfeiffer and Ehrlich; (7) large doses of immunizing bodies raise the affinity between these and the corresponding accessory factors; (8) these factors play no part in the action of specific antitoxic sera in the organism; (9) active typhoid immunity of guinea-pigs depends upon the circulation of a specific immunizing serum in the body of the animal and is thus hematogenic and not histogenic; (10) artificial resistance against certain infections following the injection of different non-specific substances has some other cause than the ordinary accessory factors; (11) a permanant increase of the accessory factors within the body has not been artificially produced; (12) these factors are of an albuminoid composition; (13) these factors are multiple in their nature, yet certain kinds

are common to ordinary research animals; (14) the leucocytes are surely a source, but not the only one of these factors.

Bacillus Coli Communis in River Water.—The presence of the bacillus coli communis in river water as an index of the self-purification of streams has recently been investigated by E. O. JORDAN (*Jour. of Hygiene*, July, 1901). His work consisted of a series of bacteriological examinations of Illinois River water, a stream abundantly contaminated by Chicago sewerage. After a pulmonary inoculation of the water into carbol-broth (1 c.c. of a 1 per cent. solution of carbolic acid to 9 c.c. of sterile bouillon), which was then incubated at 38° C. for twenty-four hours, he "plated" from this into loctose letinus agar. All colonies which produced a red color were isolated and tested for indol production, gas production and milk coagulation. Those colon bacilli which were thus isolated were not as a class gas producers. The further away from the source of contamination the water was taken, the smaller was the number of colon bacilli found, and this reduction in number was greater than could be accounted for by mere dilution. The season of the year had no effect on the number of bacilli present. The typhoid bacillus being more easily influenced by deleterious conditions than the colon bacillus, he believes that the presence of the latter is the best criterion in examination of river waters for the presence of the former.

Trichocephalus in Infection of the Appendix.—J. GIRARD (*Annales de L'Institut Pasteur*, June 25, 1901) cites a case to support the view expressed by Metschkinoff that the trichocephalus may not only produce a condition of appendicular colic, but may also act as an agent of infection and produce a true inflammation of this organ. The patient, two weeks convalescent from typhoid fever, developed a condition of abdominal tenderness accompanied by pain in the right iliac fossa, with a rise in temperature to 101° F. Laparotomy was performed, a seropurulent fluid being found in the peritoneal cavity, with distention and congestion of the intestine and in places the formation of a fibrinous pseudo-membrane. The appendix was apparently normal, but upon resection and examination was found to contain two round masses which proved to be portions of a trichocephalus. On examining the mucous membrane a similar body which showed itself to be the anterior extremity of this parasite was found embedded in it. As this parasite in its normal habitat plays a rôle more or less septic, he believes that under certain conditions it is able to invade the mucous membrane of the appendix and act as an infecting agent to the same.

Formic Aldehyde and Metabolism in Children.—T. W. TUNNICLIFFE and OTTO ROSENHEIM (*Jour. of Hygiene*, July, 1901) remark that biological interest in this substance consists in the fact that it has long been regarded as forming the first product of plant assimilation and has recently been actually demonstrated as such in plants. It undergoes polymerization under the influence of simple reagents resulting in the formation of sugars, which leads to the belief that it is an essential link in the formation of the complex carbohydrates of plants. It has recently been held as the only possible source of proteid anabolism. Its interest to the physiological chemist is that it energetically combines with the proteids and to a less extent with the carbohydrates, effecting considerable alteration in their physical and physiological properties. This behavior seems to be directly antagonistic to the biological rôle above described. After observations upon three children lasting from twenty-one to twenty-eight days, they draw the following interesting conclusions: (1) In healthy children formic aldehyde in doses of 1-5,000 in milk or 1-9,000 in total food and drink exerts no appreciable effect on the nitrogen or phosphorus metabolism or fat assimilation. The analytical figures, however, suggest that it has a tendency to diminish the phosphorus and fat assimilation and hence it may be inferred that in larger doses or if continued for a long period it would act in this direction. This effect is referable to an influence upon pancreatic digestion; (2) in healthy children in the above doses it produces a retention of water in the body; (3) in delicate children in the above maximum dose it has a chemically measurable deleterious effect upon the nitrogen. Phosphorus and fat assimilation again due to its action upon the pancreatic digestion combined with a slight intestinal irritative effect. There was a slight tendency to stimulate the katabolism of proteid material; (4) in delicate children it increases the volume of the urine and the weight of the feces; (5) in all cases the excretion of lecithin in the feces was diminished, probably due to its stimulating action upon the lecithin-splitting ferment of the pancreas; (6) in no instance did it exert any appreciable intestinal antiseptic action; (7) in no instance was there any effect upon the general health of the children.

Injections in Syphilis.—As disadvantages of the usual inunction treatment of syphilis, M. STERN (*Münich Med. Woch.*, July 2, 1901) mentions the uncleanliness, the inexact dosage, and the frequency with which the cure is interrupted by the patients themselves, the result being the present increase of tertiary and parasyphilitic affections. Injection, on the contrary, are convenient and easy of administration, rapid in action, and possess the further advantage that the physician need not leave the greater part of the treatment to the discretion of the patient. In cases in which there is a diseased or senile skin, the absorption of mercury is much diminished and in-

jections become an absolute necessity; when a rapid diagnosis has to be made they are far superior to inunction. Concerning the use of insoluble or soluble mercurials, opinions are divided, but the former possess the advantages that they have to be given less often and that from six to ten injections generally suffice. The author has tried the various salts and combinations recommended, and finds that calomel generally causes too intense pain, while gray-oil injections are liable to be followed by infiltrations and abscesses. The best results have been obtained by him with sublimate.

Larvæ of Anopheles and Culex in Winter.—Bruno Galli-Valerio and P. Nabrel (*Ctblt. für Bäk.*, June 27, 1901) have undertaken experimental research in regard to the presence of the larvæ of these insects during the winter months. They examined the water of frozen marshes and found during January and February many larvæ of the *Anopheles* but very few of the *Culex*. These, however, became abundant in the latter part of March. They explain this on the ground that the *Culex* is able to develop in from thirteen to seventeen days, while the *Anopheles* requires thirty days for this purpose. Therefore many of the last larvæ of the *Culex* in the fall would have time for development before cold weather set in; while, on the other hand, most of those of the *Anopheles* would hibernate.

Gastroptosis.—According to M. Hayem (*La Méd. Moderne*, July 12, 1901) in the etiology of gastroptosis there is a typical difference between the sexes. Gastric dilatation is more common among men, while certain mechanical causes in women have no counterpart in the opposite sex. Rickety thorax, the transversely flattened phthisical thorax, and spinal curvature, are causes common to men and women. Pressure in the hepatic region tends to interfere with the evacuation of the stomach by causing counterpressure of the duodenum against the spinal column. Relaxation of ligaments may be due to rapid emaciation or to pregnancy. Where chronic gastritis is associated with gastroptosis attention should first be directed to the latter condition. Mechanical support should be supplemented by persistent massage. Soft diet is advisable; and to facilitate the evacuation of the stomach the patient is instructed to remain recumbent for an hour or two hours after meals. Constipation is treated by intestinal massage, injections of oil or rectal irrigation.

Merits of Bipolar Version in Placenta Prævia.—In placenta prævia a fatal result is usually due to hemorrhage or sepsis. The hemorrhage is unavoidable and incident to dilatation of the os. Consequently the method requiring the least degree of dilatation necessary to perform version should give the least hemorrhage. The artificial dilatation sufficient to perform bipolar version is comparatively safe, says H. D. Fry (*Am. Gyn. and Obstet. Jour.*, July, 1901), while that necessary for the insertion of the hand and internal version is dangerous. Thirteen cases treated by Behm according to the method of dilatation and version gave four maternal deaths; forty cases were treated by bipolar version and slow delivery without the loss of a single mother. Nine cases of bipolar version were observed by Fry; all the mothers recovered.

An Anatomical Tonsillotome.—W. Stuart-Low (*Lancet*, June 29, 1901) states that tonsils usually enlarge downward so as to maintain their anatomically elliptical form. Consequently with the ordinary tonsillotome having a round hole the lower segment of the gland is imperfectly removed. He finds that if the opening be made elliptical with the major axis at right angles to the axis of the instrument all such difficulties will be obviated.

Topography of the Vermiform Appendix.—P. Muller (*Centralbl. f. Chir.*, No. 27, 1901) states that in the majority of operations upon the vermiform appendix it is easy to find the organ from the ileocecal juncture and caput coli, but when an abscess is present and the coils are much matted together these landmarks are frequently of little value. There is, however, one serviceable and ever-present pointer in the longitudinal bands. The anterior is the best and may be traced even with adhesions over it. At the point of union of these three bands the appendix is always found.

Empyema of the Frontal Sinus.—The symptoms of acute suppurative inflammation of the frontal sinus usually come on a week or two after the subsidence of the causative coryza, says E. F. Ingals (*Jour. Am. Med. Assoc.*, July 27, 1901). The most common symptoms are photophobia, pain in the eye, larcrimation, pain in the supra-orbital region. The pain is apt to come on in the morning, last a few hours and then pass off until the following morning. Not until the second week does pus appear in the naris; the flow of pus is much diminished at night. Anatomical variations render transillumination an uncertain aid to diagnosis; unusually dense walls or actual absence of the sinus will give a shadow and suggest pus where there is none. In probing the frontal sinus a silver cannula may be used, attached to a small syringe; air forced into the cavity will cause a discharge of pus or air-bubbles. Acute cases call for the use of warm and soothing detergent and antiseptic sprays, watery extract of adrenal glands or the guarded use of cocaine to promote free drainage. In chronic cases with marked ocular, orbital or cerebral symptoms, and in the more violent types of the disease with severe pain, an external operation should be done at once.

Diagnosis of Pancreatic Disease.—The fact that bacteria flourish upon the products of digestion of albumin and by their action pro-

duce the substances which are ultimately excreted in the urine as ethereal sulphates has led to the supposition that if their food was reduced in quantity by the absence of pancreatic digestion the amount of these sulphates normally present in the urine would be much lessened. D. L. EDSALL (*Proceedings of Phila. Path. Soc.*, July, 1901) has investigated two cases along this line. The first case was proven by autopsy to be carcinoma of the pancreas and the second by the clinical course to be a prolonged catarrhal jaundice without any evidence of pancreatic involvement. The first showed much decrease in the quantity of this substance daily excreted and the second gave an increase in the same. He thinks a positive result with this test is of great value as a diagnostic sign of pancreatic disease, except when gastric hyperchlorhydria, diarrhea or a milk diet are present. These latter have also been shown to be associated with low urinary values for the ethereal sulphates. A negative result would, however, be valueless, as it is probable that intestinal bacteria under certain conditions are able to break up enough undigested albumin to keep the excreted amount of these substances normal. As regards the presence of fat in the stools, icterus and active intestinal disease are able to cause the abundant presence of soaps and fatty acids and only the presence of a large amount of neutral fat is indicative of pancreatic disease.

A New Intestinal Suture.—H. LITTLEWOOD thinks (*Lancet*, June 29, 1901) that the ideal intestinal union is that which is made without any mechanical device like the Murphy button. He has tried the following simple suture with great success and rapidity. The operation is practically the same for gastro-enterostomy and entero-enterostomy. Therefore the description of either will suffice. The aim of the procedure is to avoid the accidental and occasional union of the mucous membrane across the opening after the operation has otherwise succeeded. At the selected points in the stomach and intestine the layers are divided one at a time until the mucous membrane is in view. Then the muscular and serous coats are carefully separated for a distance of 1.00 to 1.50 c.m. on all sides. Then the mucous membrane is cut and then trimmed out until the point of separation is reached. This makes the opening in the mucosa greater by the 1.00 to 1.50 c.m. trimming than that in the other two coats. The edges of the mucosa are now sutured with ordinary catgut, the redundancy in the other two coats is accommodated by snipping. Next these two layers are united with their broad raw surfaces apposed. The advantages are that the mucous membrane hole is the largest, that the broad surfaces in the outer layers unite most strongly and quickly and that the entire procedure is without any mechanical device like buttons and requires after a little practice only fifteen minutes for its performance.

Lupus Vulgaris Cured by Urea.—In the treatment of constitutional tuberculous troubles hygienic remedies have certainly been proven to be of far more value than the use of any specific drugs, and it is with a great deal of regret that the medical profession has been obliged to admit its inability to materially alter the course of this most prevalent disease. Recently some work has been done in the use of uric acid and urea in the various tuberculous lesions, the idea having originated from the well-known observation that this disease seldom occurs in markedly rheumatic or gouty persons. A. H. BUCK (*Practitioner*, July, 1901) has reported a very severe case of lupus involving the face, nose and mucous membranes of the mouth and nasal cavities. This case underwent all the ordinary methods of treatment and gradually grew worse, the duration of illness lasting about ten years and was preceded by a history of tuberculous joints and glands. Last April he was given urea, gr. xxx t.i.d., and this was gradually increased to gr. j. In about two weeks' time the edges of the ulcers became more healthy in appearance and with astonishing rapidity the lesions have been healing until now when no ulcerated area can be found. No other change was made in the habits or treatment of the patient and the results seem to have been entirely due to the urea administered. No bad symptoms occurred even when doses of one dram were given.

Frequency of Typhoid Bacilli in the Blood.—R. I. COLE (*Johns Hopkins' Hosp. Bull.*, July 1901) made cultures from fifteen cases, taking the blood directly from the veins at the bend of the elbow. In eleven cases the typhoid bacillus was cultivated. The cases included those of moderate severity as well as those of great intensity. Positive results were obtained at various stages of the disease, most of them during the second week, the earliest on the sixth day, the latest on the twenty-seventh day. In five cases the cultures were positive before a positive Widal test (dilution 1-50 in one hour) was obtained. Cultures were made from the urine in twelve of the fifteen cases and the bacilli were isolated from six. It is evident that cultures from the blood have definite clinical importance, especially where the Widal reaction is delayed.

Value of the Arloing-Courmonts Serum Reaction With Respect to the Recognition of Tuberculosis in Swine.—MAX BECK and LYDIA RABINOWITSCH (*Ztschrift. für Hygiene u. Inf.*, June 18, 1901) have instituted a series of experiments in regard to this subject. They examined one cow and eight calves, these last having been inoculated with human tuberculosis six months earlier. The cow showed the agglutination plainly in a 1 to 20 dilution, yet on autopsy and bacteriological examination no signs of tuberculosis were found. Of the inoculated calves only two showed the reaction in a 1 to 10 dilution. One calf inoculated

in the eye and which showed there a cheesy degeneration gave no reaction. The remaining five calves showed the reactions only in a 1 to 5 dilution, yet all were tuberculous. They conclude that in swine a positive occurrence of the reaction does not necessarily mean a diagnosis of tuberculosis and that a negative result does not exclude it; therefore it is not suitable for employment as a means of such diagnosis with respect to these animals.

Roentgen Rays in Diagnosis of Pulmonary Tuberculosis.—Another valuable means of diagnosing early cases of tuberculosis has been furnished the clinician in the use of the fluoroscope and skiagraph. Small infiltrations can usually be made out without any difficulty provided the observer has had sufficient experience. This method of confirming other physical signs is now widely used and several points of value are mentioned by E. C. BEALE and H. WALSHAM (*Practitioner,* July, 1901). The tube should be placed from twelve to twenty inches from the patient to avoid the divergence of the rays. In using the skiagraph it is usually not necessary to give a longer exposure than two minutes, since the rays are able to penetrate the more solid tissues after a longer time and the finer shadows may be lost. In tuberculous disease the shadow cast is of larger extent than the lesion as estimated by other clinical methods. Since a pure culture of tubercle bacilli or isolated tubercles on mucous membranes fail to throw a shadow, it is believed that the presence of a shadow means a definite deposit of tubercles. It is also possible at times to diagnose the cause of the lesion which casts a shadow, whether it be fibroid changes, fluid or tuberculous infiltration. The characteristic feature of fibroid changes and thickened pleuræ is a linear and streaky appearance as opposed to the flocculent and spotty appearance of the tuberculous shadow. Serous fluid casts but a faint shadow while purulent accumulations throw very dark shadows neither mottled nor streaky.

Inebriety.—This question which has such an important bearing upon the social status of the community has been thoroughly investigated by C. L. DANA (*Med. Rec.,* July 27, 1901) during a long service at Bellevue Hospital. He finds that about ninety per cent. of inebriates give a history of having parents addicted to the same habits and he believes that it is largely a matter of habit and environment. Of 1,560 cases one-third of them were laborers, a large percentage being furnished by clerks, tradesmen and drivers. Professional men compose about three per cent. About two-thirds of the cases are men, one-third women. The habit is unusually acquired before the age of twenty and almost always before thirty. Among the serious cases, the average duration of life after the habit was acquired was fifteen years, the maximum being over forty years. Even among those best fitted to withstand the effects of this poison, it takes about fifteen years to bring on the final dementia and insanity and it is estimated that during this time they consume about two thousand gallons of whiskey. A man of fifty-five had been drunk twice a day for three years. He suggests as agencies for preventing and lessening the injury done by this drug: (1) teaching; (2) control of the sale; (3) avoidance of transmission of degeneration through marriage of alcoholics; (4) personal supervision of those who become inebriates. The treatment may be divided into the ideal and the practical. The first would consist in the commitment of the patient to a thoroughly equipped State institution for at least six months or a year and not allow him to leave as soon as he had recovered from his debauchery. As this is impossible the patients must be sent either to the "cure" or treated at home in some such way as this: He should stop drinking and smoking and take for three weeks a mixture:

℞ Tinct. nux vom..... ℥i
Tinct. capsici ..... ℥i
Tinct. cinchon. comp. ..... ℥v

M. et Sig. One ounce t.i.d. and increase by 20 drops daily to half an ounce three times a day. The maximum dose should be continued for a week and then reduced as it was increased. Two drams of sodium bromide should be given daily when nervousness appears. The patient should be fed well and avoid getting tired or hungry. When the desire for drink returns he should take two drams of above mixture and add $^1/_{20}$ grain of atropine. At the end of two weeks the course should be repeated.

Diphtheria as a Complication of Measles.—From an analysis of 157 cases of measles with diphtheria D. N. BLAKELY and F. G. BURROWS (*Boston Med. and Surg. Jour.,* July 25, 1901) conclude that the earlier in the course of measles diphtheria develops, the more serious it is. Among fifty-four fatal cases death was due in thirty-four cases to the diphtheritic poison alone, twenty-one cases showing early extension and toxemia, ten cases later nerve degeneration. The importance of early diagnosis is obvious. Nasal obstruction or laryngeal obstruction arising during the course of measles almost certainly means diphtheria. If the initial fever of measles disappears and there is a later sudden rise of temperature, or if the cough bcomes brassy or paroxysmal, the possibility of diphtheria must be considered. Persistent fever with aphonia signifies diphtheria as a rule. When the ordinary serous discharge becomes mucopurulent or glairy, cultures should be taken. In all obscure cases give the patient the benefit of the doubt and administer antitoxin.

Sulphate of Copper in Affections of the Eye.—Besides being the classical mode of treating trachoma, the use of bluestone has recently been found to be of great value in relieving various chronic conditions of the cornea and conjunctiva. J. H. CLAIBORNE (*Med. Rec.,* July 27, 1901) reports a number of cases

illustrating the conditions which he has found to be markedly benefited by the use of this remedy. He believes that in all acute attacks of inflammation of the cornea in which there is thickening with a succulent velvety appearance of the lid and in all recurrent attacks of superficial keratitis there is an indication for bluestone. In chronic conjunctivitis attended by thickening of the lid associated with blepharitis and also in chronic dacryocystitis attended with conjunctivitis much benefit may be obtained. The copper sulphate crystal should be ground in the form of a parellelogram and then inserted into a porte-crayon. A metal probe wound with cotton should be placed in a basin of water. The upper lid is everted and the bluestone applied beneath the lid, between it and the globe. This is not washed off. The stone is then applied to the cul-de-sac of the lower lid and the excess removed by washing with the probe.

Toxicology of Male Fern.—W. GOTTHILF (*Münch. Med. Woch.*, July 2, 1901) was suddenly called to a patient in deep coma which had been preceded for two days by headache, vertigo, apathy and complete anorexia. The diagnosis at first sight seemed to rest between epilepsy and apoplexy. A hasty examination showed a rapid, regular, but thready pulse, wide pupils, increased patellar reflexes, and a tonic spasm of the entire body, especially of the arms. The rapid reaction on stimulation made it more and more likely that the case was one of intoxication. It was then found that the patient had swallowed about ten grams of pure extract of male fern for an alleged tapeworm without subsequent catharsis. The author dwells upon the importance of removing the drug with castor oil, etc., to prevent absorption and subsequent poisoning as in this case.

THERAPEUTIC HINTS.

Bronchopneumonia.—The air of the room should be well laden with moisture, as from a croup-kettle. In young children the chest should be covered with a layer of oiled silk or waxed paper over a linseed-meal poultice, which latter is replaced, when the symptoms have subsided, by an absorbent-cotton jacket. In older patients iced poultices to the chest exercise a most favorable influence. High fever calls for tub-baths or the cold pack, especially in those cases that begin abruptly. Tincture of aconite or veratrum may be employed temporarily. As a supplement to the baths, the following is good:

℞	Potass. citrat.....	10.0	(℥iiss)
	Spt. ammon. aromat.....	8.0	(℥ij)
	Spt. ætheris nitrosi.....	16.0	(℥ss)
	Liq. ammon. acetat.....	90.0	(℥iij)
	Glycerini q.s. ad.....	120.0	(℥iv)

M. Sig. One teaspoonful every two hours for a child of five years. In children a mild mercurial purge at the outset is advantageous. The diet may consist of milk, eggs, albumin and broths; the egg-white may be given in cold water or as egg-lemonade; the milk may be peptonized. A useful formula for the cough is

℞	Vin. antimonii	4.0	(℥i)
	Spt. æth. nitros.	10.0	(℥iiss)
	Tinct. opii camph.	10.0	(℥iiss)
	Liq. ammon. acet. ad....	60.0	(℥ij)

M. Sig.: A teaspoonful every two hours, for a child of three to five years.

Dover's powder is also of value. Ammonium chloride or carbonate will loosen thick sputum, but if, in spite of this, the bronchi are clogged, an emetic such as

℞	Vin. ipecac	4.0	(℥i)
	Alumini	1.3-2.0	(gr. xx-xxx)

administered every fifteen minutes until emesis occurs. As cardiac stimulants, alcohol, strychnin and especially ammonium preparations are favorites, and oxygen when cyanosis appears.—J. M. ANDERS in "Practice of Medicine."

Acute Nephritis in Children.—The treatment consists of rest in bed between blankets, milk diet, water drunk freely, and, at the start, a calomel purge followed by a mild saline, such as liquid citrate of magnesia. The body may be sponged with warm water, or a warm bath given once or twice a day, precautions being taken to avoid chill. A non-irritating diuretic is the citrate or bitartrate of potassium, which may be given in water with lemon-juice and sugar. The severe cases with dropsy, fever and suppression of urine must be treated actively by dry cups on the lumbar region, by purgation with an active saline (magnesium sulphate), and by free sweating by a hot-air bath or hot pack. A daily irrigation of the colon with normal salt is of value. If uremic symptoms set in, bleeding is the most certain means of relief, two to six ounces of blood being drawn from a child of five years. A full and bounding pulse requires nitroglycerin; threatened convulsions demand bromides and chloral by enema. The patient should be confined to bed as long as there is a trace of albumin in the urine, unless chronic nephritis is seen to have developed. The post-nephritic anemia calls for iron, preferably Basham's mixture.—W. M. POWELL in "Diseases of Children."

After Weaning.—After a child is weaned, it should not be fed oftener than once in four hours, with eight hours' rest at night. The first morning bottle should consist of eight ounces of cow's milk, the second of five ounces of cow's milk and two ounces of barley-water, preceded by the white of a raw egg fed with a spoon. The third feeding is eight ounces of milk, and the child may be allowed to nibble half a piece of the ordinary zwieback. The evening meal consists of six ounces of cow's milk, and two ounces of barley-water, and the last feeding for the night, of eight ounces of cow's milk.—L. FISHER in "Infant-Feeding in Health and Disease."

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, AUGUST 3, 1901.

BIRTH INJURIES AND NERVOUS SEQUELÆ.

There is a growing persuasion among specialists in nervous and mental diseases that injuries inflicted on the head of the child during the progress of difficult and protracted labor are responsible for many more of the serious nervous and mental conditions that sometimes develop in after life than has been supposed.

Dr. Andrew F. Currier, in his article on "Injuries of the Head in the Newborn" on page 161 of this week's Medical News calls renewed attention to this very important question. It has been too much the custom to think that the brain tissues of the newborn are capable of standing with impunity much more traumatic abuse than those of the adult. Because irregularities of the skull produced during the molding process of a protracted delivery very frequently disappear completely within a short time after birth, it has been considered justifiable to assume that the underlying soft tissues also undergo *restitutio ad integrum* and that no serious effects need be feared.

Despite this common impression to the contrary, infantile cerebral tissues are extremely delicate and it requires but very little traumatism or even only unfavorable conditions of nutrition to produce serious lasting ailments. Some years ago when the problem of the easier delivery of children through contracted pelves was being solved by the production of labor from four to six weeks before term, it was found that children thus prematurely delivered often failed to develop normally. Mental defects were not rare in such children, apparently because the delicate brain found normal development impossible under the unusual conditions of extra-uterine life. It is evident, therefore, that we cannot presume on the unsusceptibility of these young brains to injury. Moreover careful review of the history of cases of serious nervous disease that develops later in life shows that a difficult and often an instrumental labor is apparently the most important element in the etiology of the condition.

German authorities are coming more and more to the belief that so-called idiopathic epilepsy is really due in the majority of cases to injuries received during birth. There has not been any doubt in the minds of most physicians for many years that many of the cases of idiocy and impaired intellectual power are due to labor lesions.

Two lessons are emphasized by these considerations of the possible lasting effect of injuries received during labor. The first is the rule of absolute abstention from interference with the normal course of delivery unless necessity demands it. Parturition is an eminently individual process. No general laws can be laid down for the length of time it shall last in any given case. Only the special indications of the particular case can justify artificial aid in delivery. It seems confessedly true that the forceps are used too much. We do not agree with those who assert that the instrument has done more harm than good. We even wish to recall for the sake of its precious lesson the fact that the timidity of an accoucheur in the delivery of a queen of England gave Queen Victoria the throne, for it is said that the timely use of the forceps would have saved the life of England's preceding queen and given another heir to the throne. The forceps have a distinct and extremely useful place in medicine, but they are undoubtedly responsible for manifold evil and only positive indications justify their use.

The other lesson with regard to birth injuries of the head is well brought out by Dr. Currier. It is that pathological conditions about the cranium, especially those which involve the bony structures should be treated in the same manner

as corresponding lesions that occur in patients at later periods of life. Bone depressions should be elevated without delay. Fractures of the skull should receive the most careful attention, so that as far as possible the occurrence of internal ridges of bone shall be avoided. Whenever labor has been difficult or protracted, a careful examination should be made very shortly after the infant's birth in order to detect any lesion that may have resulted. The realization of his duty in this matter will itself act as a deterrent on the obstetrician who might be tempted to terminate a slow labor artificially because of its time-taking protraction.

The saving of even a few children from hopeless idiocy or lifelong nervous affections is enough to encourage the use of every conservative means during and after parturition. Undoubtedly some of the alarming increase in nervous and mental diseases in recent years is due to a neglect of proper precautions with regard to labor and properly applied surgery after its termination. No effort in this direction should seem to be too costly, for no price is too high to pay for even a slight reduction in the number of nervous and mental conditions that may with some considerable show of reasonableness be attributed to birth injuries.

PROPHYLAXIS OF CHILD TUBERCULOSIS.

THE medical profession has taken as its serious task for the twentieth century the eradication of tuberculosis. Needless to say, the success of the antituberculous campaign depends to a large extent on the health and strength of the children of the generation, their protection from opportunities of infection, and their careful treatment in an early stage if the disease is acquired. This feature of the tuberculosis movement, so prominent throughout the medical world, has been more neglected in America than have other phases of this great humanitarian advance. Children with beginning tuberculosis of the lungs or even with well-developed scrofulous tendencies need care in country homes and sanatoria more than any other class of cases. If the pulmonary symptoms are at all prominent, however, there is a well-grounded objection to the reception of such children among other child patients.

As yet the tuberculosis sanatorium movement has not progressed to the point in this country where special institutions of this kind for children can be looked for. The need for them is evident. The battle with tuberculosis among the adult population will prove indecisive until the great source of recruits to the ranks of the tuberculous that constantly exists in neglected children, can be completely cut off. In Europe, especially in Germany and France, this necessity for special care of exposed and predisposed children has been recognized. In the neighborhood of Paris there are two special institutions for the care of tuberculous children; one with 120 beds for the care of patients between three and twelve years of age; the other with nearly 250 beds for children from two to sixteen years of age. The accommodations for patients are, of course, very limited for the needs of the immense French capital, but even this unsatisfactory arrangement represents a distinct advance from the almost complete neglect of tuberculous children a few years ago. A feature of the French children's sanatoria is the existence of two ancilary institutions in the country in which, after they are pronounced cured, children may remain for some time until their health is well established, light work being provided in the meantime by which they may aid in their own maintenance. This feature is almost ideal in its thoughtfulness and prevision and must be most effective in preventing early relapses.

Until private charity and public interest have led to the establishment of similar institutions in this country, all our efforts must be concentrated on the prophylaxis of tuberculosis in the young. The report of the German Central Committee for the Suppression of Tuberculosis points out that the most effective means we have at present for the prevention of child tuberculosis is the care of the health of city children, especially during the summer. As the result of their insanitary surroundings, and because of their low resistive vitality during the developmental period, young children are especially liable to offer a favorable soil for the successful inoculation of the tubercle bacillus. This adds greatly to the amount of tuberculosis present in tenement-house districts. It is from these overcrowded quarters of the city that tuberculosis is carried to the residence districts of the well-to-do classes. Summer outings for poor city children are therefore not only a commendable public charity, but also a distinct means of lessening the death-rate from tuberculosis . The German Central Committee is able in its recent report to show that

cities where summer outings for children are encouraged have a distinctly lowered death-rate from tuberculosis.

Two special precautions with regard to the development of child tuberculosis have been particularly insisted on in recent years. One is the additional care needed for children who have suffered from either measles or from any form of pleurisy, especially if they are of delicate constitution. French authorities maintain that pulmonary tuberculosis seldom develops in children, except in cases where there has been a preceding attack of measles and that in some way this exanthem very favorably influences the tissue soil for the reception of the tubercle bacillus. It is now known, of course, that most pleurisy of obscure origin is really due to latent tuberculosis. Even where some other germ is at work the lowered vitality of the lungs invites the development of tuberculosis.

With regard to the influence of the diet of children on the development of tuberculosis two interesting facts in comparative pathology seem worthy of special notice. It is now definitely settled as the result of careful investigations at the Pasteur Institute that avian and human tuberculosis are but modified forms of the same disease. Fewer birds than has been thought die of tuberculosis. The majority of bird victims of the disease occurs in those species that live on grain. Among the meat-eating birds only those that have consumed the flesh of tuberculosis animals suffer from the disease. The application of these observations to human pathology is obvious. Children must not be allowed to live on a too-exclusively vegetable diet. Milk must form the important part of their diet until they became meat-eaters to a considerable extent. In the meantime every precaution possible must be taken to avoid the use of milk contaminated by tubercle bacilli.

TRAINING AS A THERAPEUTIC METHOD.

Some of the greatest surprises in successful therapeutics toward the end of the last century came from the application of methods of training in order to make up for apparently hopeless deficiencies in various functions.

When Dr. Urbantschitsch of Vienna announced that he had been able by means of properly regulated hearing exercises to make supposedly deaf patients understand the significance of sounds, his declaration was received with almost complete skepticism. Clinical experience with the method of hearing exercises elaborated by him soon demonstrated that the presumably deaf could in many instances be trained to hear most of the sounds originally outside the sphere of their hearing faculty.

When Fraenkel, a Swiss neurologist, announced that patients suffering from locomotor ataxia could be trained so as to regain much of their lost coördination, his claims were received very generally by neurologists with a smile of incredulity. It was pointed out that the paths which carried the impulses necessary for coördination were hopelessly degenerated, practically destroyed, and that nothing could compensate for this loss and no treatment restore lost function. Notwithstanding the apparent conclusiveness of this *a priori* reasoning events proved that Fraenkel's claims were substantially correct. Tabetics can be retaught to make movements without much of the ataxia that they exhibited before. They learn to walk again after having been bedridden for years; they are able to walk without the support they deemed absolutely necessary for even limited movement. Above all, they regain confidence in their power to control their movements and so are able to take up their lives in the open air once more.

Now comes the announcement that Dr. Keller, the director of an institute for the blind in Vienna, has been able to train a child supposedly born blind to see and distinguish many objects that vision had failed to discern before. Herr Keller's patient was a seven-year-old boy in whose external visual apparatus no defect could be detected. The transparent media and the eye ground were perfectly normal. Defective vision was evidently due to some lack of cerebral development or failure of function at the visual centers. This is usually considered to be the most hopeless form of blindness. For this functional disturbance, as in the case of the degenerated sensory columns of the cord in locomotor ataxia and the defective auditory centers in congenital deafness, therapeutics, it would seem, is not without avail. It is evident that training can enable even the naturally inadequate nervous system to perform its work, although it may be imperfectly.

The rationale of the improvement in all these cases seems to be that more concentrated attention is required to direct the defective nervous organization and that patients do not learn of

themselves how to expend the additional energy needed to the best advantage.

Director Keller has taught his first little patient previously blind to all ordinary impressions, to distinguish colors, forms and even objects. A beginning, at least, has been made in reading. His method of training commences with the simplest test, the discernment of light from darkness. The child in a dark room is asked to look in the direction in which a moving circle of light is directed. When he is able to detect light from darkness, various objects are placed within the circle of light until he recognizes them by sight. Colors are placed in a strong light and the patient learns after practice to distinguish them. After a time ordinary daylight serves to illuminate objects sufficiently for discernment, even lines and writing may be seen and its significance realized.

That much may be accomplished by training in making up for congenital defects is now generally conceded. As a therapeutic method, however, it is not practised as much as the benefit to be derived from it would warrant. In our day when, for instance, constipation has become so common and in some cases so obstinate as to make many physicians believe it an hereditary characteristic in certain families, this therapeutic principle should receive careful attention. Drugs inevitably fail after a time and only habit and training can be depended on to make up for the naturally sluggish peristalsis. With regard to neurotic manifestations of various kinds, due training in the control of the nervous system represents the most hopeful side of modern treatment as far as ultimate lasting improvement can be expected. Patients whose nervous systems are the source of functional disturbance in many organs can be trained to regular habits of life and then to the neglect of nagging symptoms that have been making life miserable.

Much of the modern charlatanry in the matter of suggestive cures, hypnotic therapeutics, psychophysical influences, osteopathic treatment, Christian Science healing, owes its success to the application of the principles that underlie and the methods of training that have been so successfully developed by the distinguished members of the medical profession. The power for good contained in these therapeutic methods must not be lost sight of by the general practitioner. On this more than drugs depends the successful treatment of chronic disease, due to some congenital or acquired nervous defect. When it was the custom to consider more carefully than now the temperaments of patients who came for treatment, with the idea of correcting temperamental influences, the old practitioners with an armamentarium much more limited than ours of the present day often accomplished results that seem impossible at present. The lesson seems worth the learning again even though its best recent exemplification has been left to quacks.

ECHOES AND NEWS.

NEW YORK.

Sanitary Conditions at Coney Island.—The sanitary condition of that portion of Coney Island known as West Brighton has during the past week been the subject of much adverse comment from the secular press. Investigations show that the reports have not been exaggerated and that the entire district greatly needs a thorough overhauling from a sanitary standpoint.

Water Scarce in Astoria.—Shortages are becoming chronic in the water department in the Borough of Queens. A few weeks ago it was a shortage of cash and now it is a shortage of water. Several large factories which have been recently built are drawing most of the water while the household consumers are left to suffer.

German Hospital Society of Brooklyn.—There is every reason to believe that a thorough reorganization of this society and the institution under its charge is impending. Judging from recent reports it would appear that a good deal of the talk about the poverty of the hospital has been exaggerated for there are many thousands of dollars in the maintenance fund and an almost equally large sum is at hand for whatever improvements may be found desirable.

Sanitary Conditions at Bath Beach, L. I.—The present sanitary condition of Bath Beach, L. I., is of the worst. Many stagnant pools of water are lying in the vacant lots and the garbage contractors are not properly performing their work. Nothing whatever has been done to remedy these evils although many complaints have been made to the Board of Health.

Hospital Bequest.—According to the will of Jacob Cullman, which was filed for probate last week, $45,000 is left to charitable institutions, $10,000 each to the Mt. Sinai Hospital, the Hebrew Benevolent and Orphan Aslyum, the Montefiore Home for Chronic Invalids, and the United Relief Works of the Society of Ethical Culture and $5,000 to the German Hospital and Dispensary.

Ward No. 13 Abolished.—For medical reasons the Binghamton State Hospital authorities have found it necessary to abolish Ward 13. It was found that this hoodoo number had a depressing effect on many patients whose

superstitions were increased by their mental infirmities. There is now no No. 13 in the State Hospital, the wards jumping from 12 to 14 for the benefit of the patients. It is the first time that the unlucky number has received official recognition by State authorities.

State Begins Serum Culture.—The work of the new antitoxin laboratory of the State Department of Health, the establishment of which was provided for by the last Legislature, has been started, as announced in last week's Medical News. The scientific part of the work will be done in a part of the Bender Laboratory building, Albany. Dr. H. D. Pease, of the Sheffield Scientific School, Yale University, has been appointed director of the new laboratory. Quarters have been secured convenient to the Bender Laboratory, which are to be fitted up as an animal house, provided with the most perfect hygienic conditions attainable for such purposes, and will be supplied with about fifteen horses for the manufacture of serum. Dr. Pease will be assisted in the work by five trained assistants. Dr. Daniel Lewis, State Commissioner of Health, says the importance of the laboratory to the people of the State can hardly be over-estimated. The Commissioner proposes to supply State institutions with diphtheria and other antitoxins free of cost, and also furnish these remedies to municipalities which are not already provided with a similar laboratory, for patients who are unable to buy them. Antitetanus and antityphoid serums will also be manufactured in the laboratory. Health officers throughout the State can now secure from the State Department examination of cultures from diphtheria patients, thus verifying a diagnosis as well as demonstrating when a diphtheria patient has so far recovered as to be allowed out of quarantine. The sputum from cases of pulmonary tuberculosis is also examined by Dr. Blumer, director of the bureau of pathology and bacteriology of the department. These new departments are intended to supply to all the health offices throughout the State the same facilities for investigation, diagnosis and treatment of infectious disease as are now supplied by the city of New York.

Outdoor Treatment of Tuberculosis.—The State Commission in Lunacy is receiving gratifying reports of the workings of the system of outdoor treatment of tuberculosis patients, instituted on Ward's Island by the Manhattan State Hospital about two months ago. Some sixty patients afflicted with the disease have been quartered during the summer in army tents having floors. They have used the tents for living and sleeping rooms, and the results reported to the State Commission are that both old and feeble patients have been greatly invigorated, and cases of formerly helpless patients show such improvement that they are able to walk about and take interest in their surroundings.

New Buildings at Central Islip.—The Commission reports that a part of the new buildings for the Manhattan State Hospital at Central Islip, Long Island, will be ready for occupancy within six weeks, when additional accommodations for 800 insane will be provided. The buildings have been in course of erection since 1898. When completed they will cover an area over one mile long. Their cost will be $1,275,000, and the cost, of their furnishings $100,000. The furnishings are being manufactured in the State prisons. When completed the new buildings will accommodate 2,300 additional insane.

Barber-Doctors Not Extinct.—A barber living up town who must have been carrying on the practice of medicine illegally for some time has become an object of interest lately to the New York State Medical Association. The fact that this man has been practising medicine was brought to the attention of the Association by a physician, the brother of a druggist, to whom the barber sent a prescription, the taking of which would have meant instant and painful death to its bearer. The druggist declined to fill it. In the course of the last year as many as fifteen cases of a similar kind have been brought to the attention of the Association.

Marine Hospital's Future.—It is now almost definitely settled that the Marine Hospital at Stapleton, Staten Island, is not to be rooted out of its venerable home there and transferred to Ellis Island. Dr. P. H. Bailhache, chief surgeon of the hospital, said to-day: "Why should the hospital and its patients be taken from such an ideal spot, overlooking the beautiful lower bay, and placed on a crowded island, so much nearer the city?" No one about the institution, from the chief surgeon down to the humblest patient, wanted to leave Stapleton, and emphatic denial was made of the recently published report that the Treasury Department officials at Washington had determined to enlarge Ellis Island by filling in on its southern shore. Originally it was suggested by Commissioner of Immigration Fitchie, that, with a slight enlargement of the island, the hospital, which comes under the jurisdiction of the Treasury Department, could be easily accommodated, and he recommended the appropriation of $100,000 by this Government to bring about the change, part of which was to go toward the construction of a modern hospital building. The present hospital and grounds are not owned by the Government, but are rented from the Marine Society of New York. Years ago it was the Old Seamen's Home, and was supported by a State tax of $2 a head on seamen. This was declared unconstitutional. Sick and disabled sailors of the merchant marine of the United States are here cared for, and there is an average of about 100 patients in the institution. Most of those admitted are afflicted with

rheumatism, fevers, or "specific diseases," and they are cared for by the hospital staff of six physicians and twenty-nine nurses and attendants. In addition to seamen, the hospital is required to treat the sick of the revenue-cutter, life-saving, coast and geodetic survey, and the light-house services, also the engineer corps of the army. Physical examinations of all applicants for admission to any of these departments are also conducted by the Marine Hospital surgeons. Four per cent. of those who apply for pilot licenses are found to be color-blind, and are accordingly rejected.

PHILADELPHIA.

Addition to St. Mary's Hospital.—The capacity of St. Mary's Hospital has been nearly doubled by the completion of the new wing begun in 1900. The addition contains private rooms, four general wards, operating-rooms, laboratory, etc., and has cost $100,000.

Trenton Insane Asylum to be Investigated.—The attendants and inmates of the New Jersey State Hospital for the Insane at Trenton have preferred charges against the management because of the food which is being furnished. The bill of fare is made up by the Board of Managers, and includes meat, vegetables and fruit. The complaint is that canned meats and practically no fruit is furnished. The hearing in the matter has been set for August 5th.

Lehigh Valley Medical Association.—The twenty-first annual meeting of the Lehigh Valley Medical Association was held in Mauch Chunk, July 25th. Dr. Chas. P. Knapp of Wyoming was elected President, and Dr. Charles MacIntyre of Easton was re-elected secretary. The winter meeting of the Society will be held at Wilkesbarre.

Transmission of Tuberculosis.—Physicians in this city are discussing with much interest the cabled reports of Koch's statements regarding tuberculosis. Local papers publish interviews with several men who are recognized authorities on the disease. Dr. J. Solis-Cohen favors the idea that the disease is not transmittable to human beings through tuberculous meat and milk, but states that it would be dangerous to take chances, and all diseased cattle should be killed. At the same time it would be a grand thing if some of the money expended by the Government to prevent the spread of tuberculosis among cattle could be expended for sanitariums. Dr. Cohen also states that there has been a decrease in the mortality of the disease in Philadelphia during the past thirty years. Formerly the deaths from tuberculosis were from one-fourth to one-fifth of the entire number. Now they are from one-sixth to one-seventh only. Dr. Lawrence F. Flick states that he has always believed that the danger of contracting tuberculosis from the milk and meat of tuberculous cattle, whilst it exists theoretically, amounts to nothing practically. Although he has for years sought for cases which could be traced unmistakably to contaminated meat and milk, he has never found one. He also believes that the greater number of cases in animals are contracted from human beings.

Tuberculosis and the Board of Health.—The Philadelphia Board of Health has taken no steps to enforce the resolution adopted by that body March 12th last, directing that "tuberculosis be hereafter included in the list of pestilential or contagious diseases required to be reported to the Health Office, etc." The President of the Bureau of Health states that no hasty action will be taken in regard to the enforcement of the resolution. Considering the attitude of other cities in regard to this question and the general war that is being waged against tuberculosis, it is rather noteworthy that this city has suspended a resolution adopted only after a most exhaustive consideration of the subject a few months since.

Failures Due to Commercialism.—Of the 407 candidates at the recent meeting of the State Medical Examiners, about 25 per cent. failed to obtain licenses. Dr. Henry Beates, Jr., President of the Board, gives the following reason for the large percentage of failures: "It is the commercialism in the medical schools. The papers of this examination prove that the medical colleges continue to admit students who are utterly illiterate; who cannot pass even the simplest rudimentary examination, and with whom medicine is a thing entirely beyond comprehension. That is the great defect. Just so long as the medical colleges admit men of little or no preliminary education, there must be a large percentage of rejections, and the granting by a college of a diploma to such a man is a fraud."

CHICAGO.

Prosecution of Dr. Betiero.—Dr. T. J. Betiero, who applied to Mayor Harrison a few days ago for a permit to bury a young man alive while in a hynotic state, has been sought by a summons taken out by the State Board of Health, alleging that Betiero's claim to be a regular physician is false.

Physicians Volunteer Aid.—Several physicians have volunteered their services in the tenement district during the summer. The list now numbers thirty nurses and doctors.

Chicago Maternity Hospital.—The directors of the Chicago Maternity Hospital would deem themselves most fortunate if Chicago generosity were to give their institution a good endowment fund. For five years it has struggled with a lack of funds, but in the midst of financial embarrassments it has continued to accomplish the purpose of its existence. It has afforded shelter, comfort, and the advantages of the best scientific treatment to several hundreds of women and children

who would have been exposed otherwise to the evil consequences that follow neglect. When one observes the character of the work done by this institution it becomes a matter of regret that it is altogether without endowment and is dependent for its support upon incidental or annual subscriptions. The officers of the hospital must be obliged to spend no inconsiderable part of their time in securing the uncertain income upon which the hospital subsists. That they should be thus diverted from their proper duties in the hospital itself must to some extent dissipate their energies and impair the quality of their work. With an endowment this difficulty would be removed. And there could be no place where an endowment would be used with greater immediate results. The hospital has passed the experimental stage. Its income could be applied at once to the uses that experience has shown to be most necessary. The man of wealth who should place the hospital beyond the reach of financial reverses would run no risk of seeing his money misappropriated. It would bring him large and quick returns.

Sterilized Milk for Children.—It may be weeks before the Health Department is able to secure the proper standard of purity in the milk supply of this city. Meanwhile the consumption of milk must continue, and must still be attended with danger. Unless the milk is subjected to some process by which animal and vegetable impurities are removed, it is not fit for invalids and young children. Even to the mature and the robust it is not without its evil effects: to the young and the weak it is likely to be fatal. It is in recognition of this state of things that some of the social settlements of Chicago have begun to provide their districts of the city with milk that has been sterilized in the settlements and is sold in is likely that many children will in this way be enabled to survive the summer. The milk is sterilized in the settlements and is sold in seven-ounce bottles at two cents a bottle, or two bottles for three cents. The selling price is low, but it is maintained at that level by the generosity of certain humane friends of the movement. The milk in its sterilized form has become popular in the neighborhoods where it has been tried, but its undoubted value has not yet received the wide recognition it deserves. The settlements concerned were obliged to attract the attention of adjacent districts by issuing cards in various languages. On these cards are described in lively terms the unwholesome qualities of the milk which often is sold in the tenement wards. It is eminently desirable that the sterilized milk should be used as widely as possible, and that throughout the city there should be a large number of depots from which it can be procured. An adequate supply of sterilized milk and a knowledge of its value, leading to the habit of using it, will do a great deal to decrease the number of deaths among young children during the hot weather. As Dr. F. W. Reilly, acting Health Commissioner, remarked the other day, one-third of the total number of deaths among infants and young children occur during July and August, and the cause is the fact that the hot weather spoils the milk. No more effective remedy could be devised than the use of milk that has been freed from all dangerous elements.

Health and Mental Strength Compared.—"Has the healthiest student the best mental equipment?" is the question which has been raised at the board of education. The answers have been so varied that the only question seeming to remain is whether the healthiest students from the normal school were given a mental test which was not in accordance with the lessons they had received at the normal school. There were 320 students from the normal school this year who expected to be made cadets in the public schools. An examination had to be held, however, outside of the tests in the normal schools because only 150 of the students could be placed as cadets. The 150 getting the highest marks were to be placed at once. Fred W. Smedley, director of pedagogical investigation, reported that the students from the normal school showed the highest physical development. He also said that the healthiest students also passed the best mental examinations. Yet when the mental test was held, the highest number of marks out of 100 made by these healthy students was about 72. The question then arose as to whether the examination had been based higher than the work done by the students in the normal school.

War Against Milk Dealers.—Names of milkmen whose supplies have been found below the grade required by law have been publicly posted on the bulletin by the Health Department. According to Secretary Pritchard, the tags that the law requires to be attached to cans containing skim milk offer no protection to customers. The tags are placed on the cans that remain in the milk wagon, while there is no indication on the smaller cans into which the milk is drawn for delivery that the cream has been removed.

GENERAL.

American Association of Orficial Surgeons.—The American Association of Orficial Surgeons will hold its next annual meeting in Chicago, September 18 and 19, 1901.

Spread of Bubonic Plague.—Despite the most rigorous measures of precaution, bubonic plague still persists in San Francisco. The thorough cleaning up of Chinatown under the supervision of the Federal authorities was completed on June 22d, and no cases of the disease appeared during the cleaning process, but it hardly had been finished when the infection broke out once more. Three cases

were discovered between July 6th and July 11th. All of them were fatal and were reported to the Marine Hospital Service in Washington.

Reports of increased mortality from bubonic plague continue to come in from United States Marine Hospital surgeons in nearly every part of the world. In Hongkong there have been 1,154 cases and 1,088 deaths, and the most rigid inspection of incoming and outgoing passengers and baggage is exercised. There were 155 deaths during the week ended June 11th. A large number of deaths daily are reported from Canton, China. Plague has been especially severe in the cities of Tung Kun and Sheck Lung on the East River. Plague is also reported from many cities in Egypt, from British India, Mauritius, Cape Colony and West Australia and Queensland. The epidemic is increasing alarmingly in Formosa, and Japanese ports are so dangerously threatened that active sanitary measures have been taken. Since May 12th, 5,716 deaths from bubonic plague in various parts of the world have been reported by United States officers. The appearance of cases of plague in the harbors of Seattle and New York is worthy of special attention.

Dr. Donaldson Resumes Practice.—Dr. Frank Donaldson, for many years a staff correspondent of the MEDICAL NEWS, has resumed the practice of his profession in Manitou, Col., and has leased Red Crag House and is ready to take a limited number of patients who are suffering from nervous breakdown or from heart or lung trouble. Phthisical cases in the first stages *only* will be received.

Damages for Breach of Secrecy.—Dr. Pader of Paris has been sentenced to pay a $50 fine and $200 damages for breach of professional secret. The plaintiff was suddenly taken ill at the house of the parents of his betrothed. The mother took the doctor apart and learned from him that the patient was a tuberculous subject. As this led to the breaking off of the marriage the patient filed the present claim.

Medical Society of the Missouri Valley.—The fourteenth annual meeting of this Society will be held at St. Joseph on September 19th and Eureka Springs September 20, 21st. One day's scientific session will be held in each city, and the last day will be devoted to sightseeing at the Springs. The scientific program promises to be full and varied. Among those to read papers are Drs. C. H. Hughes, Frank Parsons, Palmer Findley, C. E. Davis, J. W. Cokenower, W. Jepson, H. N. Moyer, F. B. Tiffany, E. S. Pettyjohn, LeRoy Crummer, J. H. Coulter and others.

Obituary.— Dr. George W. West died at the Columbian University Hospital, Washington, July 25th from the effects of the long-continued hot weather. He had been in the hospital nearly three weeks. He was overcome by the heat in his office on July 4th and his physical prostration was followed by delirium and, at times, by violent mental disorder. He was seventy years old and leaves a widow and several children.

Dr. Leonidas Russell, a medical examiner in the Pension Office and a veteran of the Civil War, died at his home in Washington on Friday night at the age of sixty-six years. He was born in Indiana, was graduated from the Jefferson Medical College, Philadelphia, and was practising at Owensboro, Ky., when the Civil War broke out. He served as assistant surgeon to the Second Kentucky Volunteers and was severely wounded in the battle of Shiloh. Dr. Russell afterward served in the Tennessee Legislature and was appointed in the Pension Office in 1885.

Dr. William Argyle Watson, who up to within two years practised medicine in New York, died at his home in Newport, July 27th, at the age of seventy-four years. At the outbreak of the Civil War Dr. Watson entered the navy as a surgeon and rendered valuable services in the Gulf of Mexico. After the war he practised in New York. He belonged to many social and patriotic organizations, his greatest interest being in the Society of the Cincinnati.

Dr. Adam Miller, one of the oldest physicians in Chicago, died Sunday at the age of ninety-one years. Early in life he was a preacher and is said to have been the oldest minister of the Methodist Episcopal Church. During the Civil War he was the family physician of Governor Richard Yates, Sr. As a scientist, particularly as an astronomer, Dr. Miller had an enviable reputation. One of the earliest diplomas issued by the medical school of the University of New York was given to him, under date of 1847. He was born in Maryland, and in 1862 went to Chicago.

Dr. Gilbert E. Palen died of pneumonia Sunday afternoon, July 28th, at his summer home in Ocean City, N. J. He was born May 3, 1832, at Palenville, N. Y., and came of Dutch ancestry. He was graduated from Yale with the class of 1853, and from the Albany Medical College in 1855. Dr. Palen settled in Philadelphia in 1877, and for many years practised medicine in Germantown. Subsequently he engaged in the manufacture of medicines.

ECLAMPSIA AND ITS RELATIONS TO THE THYROID GLAND.

H. O. NICHOLSON, at the Edinburgh Obstetrical Society, June 12, 1901, read a paper on eclampsia and its relations with the thyroid gland. During pregnancy the blood undergoes an increase in volume and a decrease in the relative proportion

of the solid elements, with a resultant falling of the specific gravity. The red blood-cells and the amount of albumin were both much diminished relatively, while the white blood-corpuscles underwent a proportionate augmentation. After thyroidectomy the blood undergoes precisely a similar change. There are other modifications of the blood in pregnancy than those mentioned. The chief one is a toxemia due directly to fetal metabolism. As the child grows older *in utero* this metabolism is more active and the toxicity of the maternal blood continually increases, so that the more advanced the period of gestation the narrower the margin of safety for the mother. Any little cause like unsuitable diet, especially chiefly a proteid one, might upset this balance against the mother and bring on the symptoms of eclampsia. A sudden chill or a cold or anything tending to congest the kidneys would act in the same manner. In pregnancy there is also hypertrophy of the cardiac muscle, and of the muscular coats of the arteries with a distinct rise in the blood pressure. It has been suggested that this tension is also due to the toxicity of the blood. The theory of true toxemia as the basis of eclampsia is now that held by the majority of obstetricians and urges for itself the following points: (1) In every case of pregnancy more or less toxemia is present, which tends to increase as the gestation advances; (2) although the fundamental factor of all eclampsia is a toxic agent, there is no constancy therein, because there is undoubtedly a variety of type in eclampsia and must therefore be several variations of the poisonous agent; (3) the toxins are produced more abundantly in some than in other cases (twin pregnancies, for example) and act as a rule more intensely in primiparæ than in multiparæ; the reasons may be that in the primiparæ mechanical pressure on the renal vessels and in the multiparæ an acquired immunity from the preceding gestations very likely obtain; (4) in spite of the toxins no alarming symptoms will occur so long as the elimination of the toxins by the kidneys is sufficiently active. As to the precise nature of the poison and as to precisely where it is formed ignorance still prevails, but it seems probable that the fetus contributes a certain share of it, because at the death of the fetus alarming symptoms usually abate. If the fetus is one or the really chief producing agent, then it is likely that nothing can be done to limit the occurrence of the poison and that in order to prevent eclampsia the elimination of the body must be maintained at its full activity, especially of the kidneys. Anything which caused renal arrest also would promptly produce the symptoms of eclampsia. Consequently the whole secret of treatment, both prophylactic and curative, was vested in finding and correcting such cause of the arrested renal function. What is it that in the midst of normal elimination suddenly threw the kidney out of gear? Lange has noted that in twenty-five pregnancies in which the normal hypertrophy of the thyroid gland did not occur, albuminuria was present in 20. Large doses of thyroidin were administered to women in whom the normal enlargement of the thyroid gland had occurred physiologically and a marked decrease in the size of the gland appeared at once. One might conclude therefore that the usual enlargement of this gland is a normal process with the purpose of meeting the demands of increased metabolism. With a continuous supply by medication of thyroidin this demand for hypersecretion was eliminated and the gland soon resumed its normal proportions. Hallion has also observed the same phenomenon and Murray acting on the same theory gave thyroidin to certain cases of goiter with marked success. Lange also gave thyroidin to a patient with pathological enlargement of the thyroid gland and that again a diminution occurred. The exhibition of large doses of this extract are not contra-indicated and no atrophying effects upon the child had been observed. In patients suffering from the albuminuria of pregnancy thyroidin acted as a certain diuretic. The author then gave the history of a multipara who in her two preceding pregnancies had had fits and in the third had gone through the first six months uneventfully, but during the seventh set up albuminuria with headache, giddines, amaurosis, general edema and puffiness. She was put to bed on a milk diet and given a diuretic mixture. During the eighth month she had a seizure which was treated with bromides and chloral. The urine was scanty and solid with albumin on boiling. Sphygmographic tracings of both radial arteries showed contracted vessels and high-tension pulse. The next day thyroid tabloids were begun and at first two, then three a day were given. After three weeks she was again about the house, with entirely normal urine and almost all of the symptoms gone. Twelve days later she gave birth to a full-term living healthy child without any untoward symptoms and with an uneventful recovery. The albuminuria did not again show itself. The edema in this woman was not of the usual type seen in dropsy, but was very general, dense and pitted only on prolonged and firm pressure. It strongly suggested true myxedema. The albuminuria was doubtless of toxic origin. This toxemia would first lead to an increase in the arterial tension and then if long enough continued would induce albuminuria. If hypuresis occurred and persisted, then eclampsia would soon follow with its usual prodromic symptoms of headache, vertigo, amaurosis, etc. Diuresis however produced had a tendency to delay the eclamptic symptoms. Hypuresis at the later period of pregnancy might be regarded as a danger point. Edema and albuminuria were not always present. A still more constant sign of danger would be continued, small, high-pressure pulse, unless accompanied by a free diuresis. Symptoms such as these might be and often are produced by defective action of the thyroid gland. Iodothyrin increases the excretion of the urea and also the other body processes. Thyroid extract has a distinct diuretic

effect on the diseased kidney, although quite negative on the healthy. It also lowers the blood-pressure and dilates the arteries. The internal secretion of the suprarenal bodies has the opposite effect and one may assume that their combined action results in a certain arterial tone. If the thyroid secretion were to become decreased, then the unchecked activity of the suprarenal bodies would be very profound in the kidneys as elsewhere. In the early stages when the pulse begins to get tense and the urine scanty, thyroid extract should be given twice or thrice daily. Iodide of potassium has been used as a specific against these early stages of eclampsia and probably acts by its iodine. This was picked up by the thyroid gland and converted into iodothyrin. It has even been suggested to give infusions containing potassium iodide instead of sodium chloride. If the convulsions have already begun mouth administration of thyroid extract would be too slow. Then fresh thyroid juice or liquor thyroidii in ten- to fifteen-minim doses should be given hypodermatically and repeated until the improvement begins. For the immediate treatment of eclampsia morphia is perhaps the best single remedy, because it not only controls the convulsions, but inhibits metabolism so that the thyroid gland can recover itself. The dose must be large, not less than half a grain to begin with. Eclamptic patients resist the poisonous effects of the drug in a remarkable way. Doses of one and one and a half grains have been given without any undesirable results. It relieves the spasm of the arteries and lowers the blood-pressure. Saline infusions have been much praised. Probably its earliest effect is to relax the arterial tension and thus produce diuresis.

OUR LONDON LETTER.

(From Our Special Correspondent.)

LONDON, July 20, 1901.

THE ROYAL MEDICAL BENEVOLENT COLLEGE, EPSOM—ITS FESTIVAL DINNER—DOCTORS AND DIET—LORD ROSEBERY AS AN AFTER-DINNER SPEAKER—HIS MEDICAL ANCESTRY—OTHER PEERS DESCENDED FROM DOCTORS—EPSOM COLLEGE: ITS PUPILS AND PENSIONERS—THE NATIONAL HOSPITAL FOR THE PARALYZED AND EPILEPTIC.

ON July 9th was held the twenty-eighth festival dinner of the Royal Medical Benevolent College, Epsom. Lord Rosebery, the President of the College was in the Chair, and between three and four hundred members of the medical profession were present. Among them were some of the shining lights of our professional firmament, such as Sir R. Douglas Powell, Sir William Broadbent, Dr. Pavy, Professor Clifford Allbutt of Cambridge, Dr. W. S. Playfair, Sir John Williams, Mr. Christopher Heath and Mr. Jonathan Hutchinson. The object of the dinner was to get money to wipe off a considerable debt, and subscriptions to almost double the amount required were announced. Lord Rosebery, who had his physician, Sir William Broadbent, on his right, must have felt like Sancho Panza when he dined in state as Governor of Baratoria with his chief physician standing behind him with a wand to indicate vetoed dishes. Broadbent, however, is not a "starving doctor," as the late Sir Andrew Clark used to be described; and, although Lord Rosebery expressed some natural anxiety at having to dine in the presence of so many authorities on diet, they made the task easier for him by openly defying their own precepts. This paradoxical feature of the medical character did not escape the notice of that keen *censor morum*, Thackeray, who at dinner, public and private, took a malicious pleasure in seeing physicians eat freely of all the meats they condemned in the consulting-room as dangerous to the internal peace of man. To me these medical dinners recall the remark of Cicero about the Roman soothsayers, for it must be hard for one great authority on diet to preserve his professional gravity in the presence of another when both are conscious of having broken all their own dietetic laws. To return, however, to Lord Rosebery. He is a capital after-dinner speaker with the light touch that prevents that species of oratory from being a nightmare, as it too often is in this country. He is a many-sided man, having been Prime Minister, having written more than one successful book, and above all having won the Derby—"the blue ribbon of the turf"—in two successive years. It was characteristic of our race that when the speaker who proposed the health of the Chairman spoke of Lord Rosebery as a sportsman, the applause was loudest and longest.

Lord Rosebery spoke of the medical profession as "one of the noblest, if not the noblest, of all professions." It is somewhat remarkable, however, that he did not refer to his own medical ancestry. Gilbert Primrose who was principal surgeon to James VI. of Scotland was the elder brother of Archibald Primrose from whom the Earls of Rosebery are descended. A son of Gilbert Primrose was a well-known physician who practised at Hull in the seventeenth century and the author of several books which achieved a considerable measure of popularity. Among them is a "refutation" of Harvey's work on the circulation of the blood. His objection to Harvey's teaching may not have been altogether unbiased, for the discoverer of the circulation was one of those who examined him for the license of the London College of Physicians.

Lord Rosebery, by the way, is not the only member of the British Peerage with a medical ancestry. Our present Secretary of State for Foreign Affairs, the Marquis of Lansdowne, is descended from Sir William Petty who was Physician General of Cromwell's forces in Ireland during the Commonwealth. Petty was a graduate of Oxford and one of the founders of the Royal Society. Besides being one of the first physicians of his day he won fame and fortune as a mechanical inventor and laid the foundations of the science of political economy in his work on

Political Arithemetick. The Duke of Northumberland, the nominal head of the ancient family of the Percies, famous in history and in legend, is not a Percy at all. The peerage became extinct in the male line early in the eighteenth century, and the heiress of the Percies bestowed her heart and hand on a physician named Smithson. To this unfortunate son of Æsculapius the honors of his wife's family were allowed to pass, and the sons of Smithson have since worn the coronet of the Percies. The present Lord Knutsford is the grandson of Sir Henry Holland, a fashionable physician of the early Victorian age. A story is told of Holland that on paying his usual professional call one day on a *grande dame de par le monde,* as old Brantôme would have said, he was informed by the hall porter that her ladyship was very sorry but she was too ill to see him. Another story is that once when Lord Palmerston had been ill some one called to inquire and met his physician, Dr. Robert Ferguson, coming out. On being asked how the famous statesman was the doctor replied, "Well, I can't give you a better proof that he is going on well than the fact that I have just taken my last fee, and Holland is to take over the case." Holland was, however, a practitioner, of great shrewdness and good sense, although never having been on the staff of a hospital, and he knew little of medicine in the technical sense. He married a daughter of Sydney Smith, one of the founders of the *Edinburgh Review* and, like Yorick, a fellow of infinite jest; Lord Knutsford has, therefore, a better ancestry than if he were the

"Tenth transmitter of a foolish face."

In the eighteenth century there practised in Edinburgh a physician named Somerville, who might have styled himself Lord Somerville had he so chosen, but like the tenth or eleventh Lord Fairfax, who recently passed away somewhere in the United States, he preferred the single prefix of "Dr."

I have drifted away from Epsom College about which, perhaps, your readers might like to know something. Founded originally as a school for the sons of medical men, it has blossomed out into a high class public school which prepared boys to take up any professional study they pleased. This it does more cheaply, but not less efficiently than the great schools of Eton, Winchester, Harrow and Rugby. There are two hundred and fifty boys at Epsom school, and as Lord Rosebery, who is their near neighbor, said the other night, no finer lads are to be seen anywhere. They win many scholarships and prizes at the Universities and medical schools and several men who stand high in the medical profession received their preliminary education at Epsom. Fifty scholars, mostly orphans of medical men, are educated, boarded, and clothed by the College free of all cost, and on leaving school get a scholarship or a grant to start them on their way. A part of the Epsom foundation, but distinct from the school, is a fund for medical men past work and in need of help, or the widows of such. There are fifty-nine pensioners who receive $150 a year each, and several recipients of smaller annuities. It is not much in proportion to the number of poor broken-down doctors to be relieved. But altogether Epsom is an institution of which the medical profession may be justly proud.

The affairs of the National Hospital for the Paralyzed and Epileptic seem to be nearing a settlement. At a meeting held on July 7th, the report of the Committee of Inquiry which, as I have already informed you, was on all essential points in favor of the staff, was adopted unanimously. The Secretary-Director whose autocratic methods of administration were the principal cause of the trouble has resigned, and a Committee of Organization was formed to draw up a scheme for the better management of the hospital. An essential feature in any scheme for that purpose, if it is to find favor with the medical staff, is the dissolution of the present Board of Management which is really responsible for the misdeeds of the Secretary-Director. Whether the staff will have its way in this matter remains to be seen.

SOCIETY PROCEEDINGS.

BRITISH CONGRESS OF TUBERCULOSIS.

SECOND DAY—JULY 23D.

As indicated in last week's MEDICAL NEWS, the Tuberculosis Congress, held in London, opened with much éclat, on July 22d, and gave promise to being a very successful as well as practical Congress.

Fight Against Tuberculosis.—This was the subject taken up by Dr. Robert Koch in the first general session held in St. James' Hall. It was delivered before an immense audience and was received with serious attention. He said that the fight against tuberculosis in the light of the facts gained in the contest with other infectious diseases offered great hope for the future and the work of the present Congress was a great step in this direction. It need not be emphasized what frightful ravages are yearly being wrought by the tubercle bacillus and when it is borne in mind that the disease is a preventable one it seems strange that it cannot be eradicated. Yet such is that inertia of deep-rooted habits that it needs the united efforts of the entire medical profession to force the attention of the lay mind to the realization of the important elements in the struggle.

Specific Needs for Different Diseases.—The most important lesson learned from this experience is that it is a great blunder to treat pestilences according to a general scheme. This was done in former times; no matter whether the pestilence in question was cholera, plague, or leprosy, isolation, quarantine, useless disinfection were always resorted to. But now it is known that every disease must be treated according to its own special individuality, and that the measures to be taken against it must be most accurately

adapted to its special nature, to its etiology. Success in combating tuberculosis is hopeful only if this lesson is kept constantly in view. The plague, cholera, hydrophobia and leprosy were discussed in turn, showing how the specific infectious agent in each was communicated in a different manner and the only efficient means of prevention was one that took this most important element into full account.

Sputum in Tuberculosis.—This, Dr. Koch holds, is the most important factor in the dissemination of tuberculosis. In by far the majority of cases of tuberculosis the disease has its seat in the lungs, and has also begun there. From this fact it is justly concluded that the germs of the disease, that is, the tubercle bacilli, must have got into the lungs by inhalation. As to the question where the inhaled tubercle bacilli have come from, there is also no doubt. On the contrary, it is known with certainty that they get into the air with the sputum of consumptive patients. This sputum, especially in advanced stages of the disease, almost always contains tubercle bacilli, sometimes in incredible quantities. By coughing, and even speaking, it is flung into the air in little drops, that is, in a moist condition, and can at once infect persons who happen to be near the coughers. But it may also be pulverized when dried, in the linen or on the floor, for instance, and get into the air in the form of dust. In this manner a complete circle, a so-called *circulus vitiosis*, has been formed for the process of infection from the diseased lung, which produces phlegm and pus containing tubercle bacilli, to the formation of moist and dry particles (which, in virtue of their smallness, can keep floating a good while in the air), and finally to new infection, if particles penetrate with the air into a healthy lung and originate the disease anew. But the tubercle bacilli may get to other organs of the body in the same way, and thus originate other forms of tuberculosis. This, however, is considerably rarer. The sputum of consumptive people, then, is to be regarded as the main source of the infection of tuberculosis. The question arises whether there are not other sources too, copious enough to demand consideration in the combating of tuberculosis. Great importance used to be attached to the hereditary transmission of tuberculosis. Now, however, it has been demonstrated by thorough investigation, that, though hereditary tuberculosis is not absolutely non-existent, it is nevertheless extremely rare and in considering practical measures this form of origination may be left entirely out of account.

Human and Bovine Tuberculosis.—This must be considered the central theme of Dr. Koch's address and the discussion which arose was most active about the ideas set forth. He said that it has been very extensively held that the tubercle bacillus might be conveyed from animals suffering from tuberculosis to man. General tuberculosis, he admits, is common in most animals, but his investigations had led him to take the position that bovine tuberculosis and human tuberculosis were different diseases and were not intercommunicable; especially he held that human tuberculosis probably did not give rise to bovine tuberculosis. In this connection he said that even in his first circumstantial publication on the etiology of tuberculosis he expressed himself regarding the identity of human tuberculosis and bovine tuberculosis with reserve. Proved facts, which would have enabled him sharply to distinguish these two forms of the disease, were not then at his disposal, but sure proofs of their absolute identity were equally undiscoverable, and he therefore had to leave this question undecided. In order to decide it, he repeatedly resumed the investigations relating to it, but so long as he experimented on small animals, such as rabbits and guinea-pigs, he failed to arrive at any satisfactory result, though indications which rendered the difference of the two forms of tuberculosis probably were not wanting. Not till the complaisance of the Ministry of Agriculture enabled him to experiment on cattle, the only animals really suitable for these investigations, did he arrive at absolutely conclusive results. Of the experiments which he has carried out during the last two years along with Professor Schütz, of the Veterinary College in Berlin, the following are some of the most important: A number of young cattle which had stood the tuberculin test, and might therefore be regarded as free from tuberculosis, were infected in various ways with tubercle bacilli taken from cases of human tuberculosis; some of them got the tuberculous sputum of consumptive patients direct. In some cases the tubercle bacilli or the sputum were injected under the skin, in others into the peritoneal cavity, in others into the jugular vein. Six animals were fed with tuberculous sputum almost daily for seven or eight months; four repeatedly inhaled great quantities of bacilli, which were distributed in water, and scattered with it in the form of spray. None of these cattle (there were nineteen of them) showed any symptoms of the disease, and they gained considerably in weight. From six to eight months after the beginning of the experiments they were killed. In their internal organs not a trace of tuberculosis was found. Only at the places where the injections had been made small suppurative foci had formed, in which few tubercle bacilli could be found. This is exactly what one finds when one injects dead tubercle bacilli under the skin of animals liable to contagion. So the animals we experimented on were affected by the living bacilli of human tuberculosis exactly as they would have been by dead ones; they were absolutely insusceptible to them. The result was utterly different, however, when the same experiment was made on cattle free from tuberculosis with tubercle bacilli that came from the lungs of an animal suffering from bovine tuberculosis. After an incubation period of about a week the severest tuberculous disorders of the internal organs broke out in all the infected animals. It was all one whether the infecting matter

had been injected only under the skin, or into the peritoneal cavity or the vascular system. High fever set in, and the animals became weak and lean; some of them died after a month and a half to two months, others were killed in a miserably sick condition after three months. After death extensive tuberculous infiltrations were found at the place where the injections had been made, and in the neighboring lymphatic glands, and also far advanced alterations of the internal organs, especially the lungs and the spleen. In the cases in which the injection had been made into the peritoneal cavity the tuberculous growths which are so characteristic of bovine tuberculosis were found on the omentum and peritoneum. In short, the cattle proved just as susceptible to infection by the bacillus of bovine tuberculosis as they had proved insusceptible to infection by the bacillus of human tuberculosis.

Desirability of Commission to Investigate This Point.—These experiments with others led Koch to express the hope that a Commission might be appointed to investigate this question thoroughly.

Can Man be Infected from Cattle?—With reference to the more important question, Is it possible for cattle, suffering from tuberculosis to infect man? he said that it is impossible to give this question a direct answer, because, of course, the experimental investigation of it with human beings is out of the question. Indirectly, however, one can try to approach it. It is well known that the milk and butter consumed in great cities very often contains large quantities of the bacilli of bovine tuberculosis in a living condition, as the numerous infection experiments with such dairy products on animals have proved. Most of the inhabitants of such cities daily consume such living and perfectly virulent bacilli of bovine tuberculosis, and unintentionally carry out the experiment which investigators are not at liberty to make, If the bacilli of bovine tuberculosis were able to infect human beings, many cases of tuberculosis caused by the consumption of alimenta containing tubercle bacilli could not but occur among the inhabitants of great cities, especially the children. And most medical men believe that this is actually the case. In reality, however, it is not so. That a case of tuberculosis has been caused by alimenta can be assumed with certainty only when the intestine suffers first—that is, when a so-called primary tuberculosis of the intestines is found. But such cases are extremely rare. Among many cases of tuberculosis examined after death, Koch remembers having seen primary tuberculosis of the intestine only twice. Among the great postmortem material of the Charité Hospital in Berlin ten cases of primary tuberculosis of the intestine occurred in five years. Among 933 cases of tuberculosis in children at the Emperor Frederick's Hospital for Children, Baginsky never found tuberculosis of the intestine without simultaneous disease of the lungs and the bronchial glands. Among 3,104 postmortem examinations of tuberculous children, Biedert observed only sixteen cases of primary tuberculosis of the intestine. From the literature of the subject many more statistics of the same kind could be cited, all indubitably showing that primary tuberculosis of the intestine, especially among children, is a comparatively rare disease, and of these few cases that have been enumerated, it is by no means certain that they were due to infection by bovine tuberculosis. It is just as likely that they were caused by the widely propagated bacilli of human tuberculosis, which may have got into the digestive canal in some way or other—for instance, by swallowing saliva from the mouth. Hitherto nobody could decide with certainly in such a case whether the tuberculosis of the intestine was of human or of animal origin. Now the diagnosis can be made. All that is necessary is to cultivate in pure culture the tubercle bacilli found in the tuberculous material, and to ascertain whether they belong to bovine tuberculosis by inoculating cattle with them. For this purpose he recommends subcutaneous injection, which yields quite specially characteristic and convincing results. For half a year past he has occupied himself with such investigations, but, owing to the rareness of the disease in question, the number of the cases he has been able to investigate is but small. What has hitherto resulted from this investigation does not support the assumption that bovine tuberculosis occurs in man.

Though the important question whether man is susceptible to bovine tuberculosis at all is not yet absolutely decided, and will not admit of absolute decision to-day or to-morrow, one is nevertheless already at liberty to say that, if such susceptibility really exists, the infection of human beings is but a very rare occurrence. He estimated the extent of the infection by the milk and flesh of tuberculous cattle, and the butter made of their milk, as hardly greater than that of hereditary transmission, and he therefore does not deem it advisable to take any measures against it.

Notification, Hospitals and Education.—Koch then went on to consider the desirability of notification of tuberculous patients to boards of health, the establishment of sanatoria, measures of disinfection and education of the public to the real dangers. In this latter connection he took occasion to praise highly the excellent work of Dr. Hermann M. Biggs and the enlightened policy of the New York Board of Health with reference to the practical measures in force looking to the education of the public on the subject of this disease. Much discussion was aroused by the reading of Dr. Koch's paper, most of which was antagonistic to his conclusions relative to the non-contagiousness, for man, of bovine tuberculosis. The matter, however, was one of evidence and the best way to settle the question was to have a commission appointed. This, it was announced by Sir Crichton Brown Tuesday evening, had been done by the British Government.

International Legislation and Notification.—This was the central theme of the paper read by Professor Brouardel of Paris. That tuberculosis

was a preventable disease no one at the present time denied. Any measures tending to limit the ravages of alcoholism would diminish the mortality from consumption. He referred to the great danger in hawking pieces of meat in public places and in the sale of milk which had not been examined. Professor Brouardel believed these dangers could be remedied by legislation. He said that the measures needed for the prevention of tuberculosis were identical in every country, and the first step in this direction was to render unhealthy dwellings and districts salubrious. A healthy house, he said, was antituberculous. He complimented the United States on its quick realization of the danger of expectoration, and on its legislation in the matter. He said once this habit had quite disappeared, tuberculosis would decrease rapidly. He dissented very radically from the views of Dr. Koch anent the difference of bovine and human tuberculosis, and also declared that the ministers of finance of the various countries should deduct from the revenue derived from the tax on alcohol, the cost of the ruined drunkard and his degenerate children who must be sheltered.

Treatment of Tuberculosis by Climate.—In the Section on Medicine, Dr. C. Theodore Williams of London gave the introductory address on this subject. The questions to be discussed were: (1) What influences has climate on the treatment of tuberculosis? and (2) how far can cases be grouped for treatment in certain climates? Both of these questions he discussed very fully. The belief that has existed in all ages that the disease is curable by climate is, he thinks, justified by the results of such treatment. Under what climatic conditions, he asks, is arrest of the disease most common? What are the real causes of such improvement and how can they be successfully brought into play? In all climatic treatment, of course, care must be taken to bring the patient fully under the influence of the atmosphere, and to endure a strictly open-air life by day and by night, with complete hygienic and sanitary surroundings, whether in a sanatorium or elsewhere.

Not All Climates Avail.—But all climates favoring an open-air life are not necessarily suitable for the treatment of consumption; tropical lands must be excluded, because there the appetite is diminished, the nervous and muscular energy depressed, excessive action from the skin induced, and requisite exercise prevented. Bacillary increase is probably also favored. Very moist climate and those in which the sun is often obscured by mist and fog, even though mild, are undesirable, as sunshine is of the greatest importance to the consumptive. The climate which best fulfils the conditions for open-air treatment need not be a very warm nor a very cold one, but should be dry and stimulating, with abundant sunshine, admitting of much exercise, and producing nervous and muscular vigor.

The Classification of Climates.—Climates, he said, must first be classified before they are described, and though it would be possible to arrange them scientifically on the basis of meteorology, as attempted in the Lumleian Lectures before the College of Physicians, for the purposes of this discussion a few practical groups will be preferable. These are (1) marine climates; (2) dry, warm climates, partly inland and partly marine; (3) mountain climates. Marine climates include (*a*) the British and Irish sea coast resorts; (*b*) the warm marine climates of Madeira, Teneriffe, and the West Indies; (*c*) Sea voyages. Dry, warm climates, the desert climates, and those of the Mediterranean basins, differing in many particulars, but both characterized by warmth and dryness. Mountain climates characterized by the influence of diminished barometic pressure. The climates discussed were those practical to use from England rather than from the United States and their extended description is here omitted. He spoke particularly in praise of extended sea voyages, especially voyages to Australia and New Zealand and around the Cape of Good Hope in clipper ships. They are most beneficial (1) in cases of hemorrhagic phthisis, where large hemorrhage accompanies small areas of tuberculization; (2) in scrofulous or strumous phthisis, where lung disease is accompanied by strumous gland or joint affections; (3) in cases of chronic cavity, where the tuberculous disease is unilateral and quiescent. To ensure the success of a sea voyage, the patient must be certain of (1) good and abundant food, (2) proper cabin ventilation, also (3) that the cruise be principally in temperate climes and not in tropical. Of the dry, warm climes the Egyptian desert is highly commended. With reference to the Riviera, the cases which do best there are (1) phthisis in which inflammatory processes have played a large part in predisposing to the disease; (2) strumous phthisis; (3) laryngeal phthisis; (4) unilateral pulmonary tuberculization rather than bilateral; (5) the large class of consumptives who either from extent of disease or feebleness of circulation, or advancing years, are unable to endure the rarefied atmosphere and cold of the high altitudes. Most of these patients love warmth, and cannot take enough exercise when the thermometer is below zero to maintain it. With reference to mountain climates his conclusions were as follows: (1) The respiration of the rarefied atmosphere produces hypertrophy of the healthy lung and local pulmonary emphysema around the tuberculous lesions, giving rise in due time to thoracic enlargement. (2) It is possible the arrest of tuberculous disease is at least partly due to the pressure exercised in the tuberculous masses by the increasing bulk of the surrounding lung tissue, which by emptying the blood-vessels promotes caseation and cretefication of the tubercle. (3) These changes are accompanied by general improvement in digestion and assimilation, the cessation of all symptoms of disease, the return of natural functions, by gain of weight, of color, of nervous and muscular activity, and of respiratory and circulatory power. (4) Arrest of disease

takes place in 58 per cent. of the tuberculization cases, and great improvement in 87 per cent. In excavation cases arrest occurs in 21 per cent. and great improvement in 61 per cent. (5) The climate is specially beneficial in hemorrhagic phthisis, and phthisis in which hereditary predisposition is strongly marked, and is well suited to chronic tuberculosis of the lungs in general, provided the extent of lung involved is not too large nor the disease accompanied by much fever. (6) Males and females seem to do equally well and to profit most between the ages of twenty to thirty. Males over forty and females under twenty benefit least. (7) The climate is contraindicated in acute phthisis, catarrhal phthisis, in laryngeal phthisis, in cases of phthisis accompanied by great nervous irritability in patients with double cavities, with fibroid phthisis, and in all patients whose pulmonary surface has been so much reduced from any cause that it does not suffice for complete respiratory purposes.

Classification of Cases.—Dr. Burney Yeo of London took up the second query as to what kinds of cases are best treated on climatic lines. He said that the main objects of treatment in pulmonary tuberculosis are (*a*) to arrest catarrhal conditions of the air-passages; (*b*) to improve nervous and circulatory tone; (*c*) to increase the activity of the digestive functions, and thus stimulate nutrition by promoting the desire and increasing the power to take exercise; (*d*) to raise the moral tone—by no means an unimportant matter—by affording a clear, bright, and cheerful environment; (*e*) to diminish by its asepticity bacterial activity.

Open-Air Treatment: New and Old.—It must be a question for consideration whether so-called "open-air treatment," without regard to suitable climatic conditions, will do all this. It should be the object when practicable to place the consumptive patient under conditions and in circumstances where, without risk or injury, he may obtain the most complete and perfect aeration of the lungs possible. The difficulties in the way of finding suitable hiding-places for the tuberculous were pointed out and Dr. Yeo cited some marvelous "cures" which occurred in patients who never left London. Many chronic stationary cases with fair general health travel about to different winter resorts with successive seasons and take no harm in doing so.

Dr. Yeo objects to the terms "incipient" phthisis and "pretuberculous" phthisis, since many mean by such "suspected" phthisis and as such are often reported cured by this or that procedure, when, in fact, they have never had tuberculosis at all. Such cases detract very largely from the value of statistics, if they do not entirely vitiate them. He advocates the expression "early" phthisis.

The Influence of Climate on Consumption.—The answer to the first part of the question, Dr. Yeo suggests, will be that a suitable climate (*a*) relieves or removes catarrhal conditions accompanying the disease in a number of cases; (*b*) it raises nervous and vascular tone; (*c*) it increases muscular energy and the ability as well as the desire for exercise; (*d*) by rendering an open-air life possible, it increases the aeration of the lungs and diminishes the activity of bacterial agencies, one of the most essential conditions of arrest and cure of the disease; (*e*) it improves the tone and promotes the activity of the digestive functions, and so enables the patient to take the large amount of food which is needed to heighten his state of nutrition; (*f*) and, finally, it improves the moral and mental state by surrounding the patient with a bright, cheerful, and hopeful environment.

The Grouping of Cases.—Then, as the answer to the second part of the question, he says: (1) Cases seen at the very commencement of the disease, and who are otherwise in good health, may be permitted a certain amount of choice in the selection of a climate, provided it allows of many hours being spent daily in the open air, and that they are placed under admittedly hygienic conditions. A choice may be made from climates of altitude, the desert climate, the inland plateaux of South Africa, the sea voyage for those with a decided liking for the sea, and suitably placed sanatoria. (2) For progressive febrile cases, repose in bed or on a couch at home, in the best conditions practicable for the free access of air and sunshine to their apartments. (3) For advanced cases home is best if the conditions of home life is favorable, or the warm marine climates with cheerful surroundings if home life is unfavorable or change is urgently desired. (4) For catarrhal cases warm, soothing climates like Madeira or Teneriffe are best. (5) For rheumatic or gouty cases of the fibroid or pleurogenic type—dry, marine climates or the desert climate are most suitable. (6) For the so-called "scrofulous cases," if free from catarrh, fairly bracing marine climates; if with catarrh, mild marine climates should be prescribed. (7) For most other moderately advanced cases, with the limitations already mentioned, the climate of the high mountains, above the cloud belts, is the most curative.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Held May 7, 1901.

The President, Joseph Collins, M.D., in the Chair.

A Case of Successful Moral Treatment of a Form of Hysteria.—Dr. Mary Putnam Jacobi reported this case. The patient was a woman, twenty-four years of age, belonging to a neurotic family. Her symptoms had begun four years before coming under observation with an endometritis and a uterine retroflexion. She had been subjected to a good deal of local treatment, including curettage and an Alexander's operation. The latter procedure had relieved the dysmenorrhea, but had been followed by a fixed pain in the abdomen not increased by pressure. She claimed to be unable to walk or stand because of severe pain in

the back and abdomen which it induced. Examination showed no motor inability, and when started she could walk very readily and energetically. The uterine disease had entirely disappeared. She was moderately anemic and quite constipated. The speaker said that at some portion of the cerebrospinal tract an area of nerve tissue must be so nearly on the border of exhaustion that an attempt at function carries it beyond this line. It was conceivable that with the exhaustion of the cerebral center the very thought of the movement would be followed by pain. According to Sanier, such hysterical pains point to a partial anesthesia in the brain. Apart from the intermittent pains excited by the sense of walking, there seemed to be a permanent and distressing sense in the back of requiring support. In a previous experience with a bedridden patient she had succeeded in making her walk within a week by the application of a Taylor spinal brace. This simple device had given great relief. The necessary nerve stimulus had been secured by the application of static electricity. This remedy seemed to be almost a specific for hysterical pains. The subject of the present report had been persuaded to leave her home and take a room near Dr. Jacobi's office. At first it was not difficult to get her to walk a portion of a block, but when finally asked to walk a whole block she obstinately refused. All sorts of changes in the treatment and methods of management were necessary in order to conquer the patient's wilfulness, yet this was essential to further progress. Her mode of life for each day was mapped out most minutely. By the most persistent and painstaking efforts exerted for a period of four months the patient was finally conquered. During the last eighteen months she had been living a fairly normal life. Dr. Jacobi said that in hysterics the habitual dependence upon fellow minds is immensely intensified. To get rid of a false idea, it must be starved out and atrophied by an entire lack of support from the minds of those around the patient. The essential element of the treatment of this case was the bringing of the personality of the patient under the control of another mind.

Dr. B. Sachs commended the general plan of treatment described in this paper, though admitting that it required far too much expenditure of time and attention to detail to make it generally available.

Psychological Method.—Dr. Ira Van Gieson expressed his admiration for the report just presented, for, he said, it was an earnest of the time when psychological cases would be treated less by medicine and more by psychology. This case afforded an example of what could and should be done in hundreds and thousands of other similar cases. He had been particularly impressed with the statement made concerning the necessity for causing an atrophy of each false idea—the reverse of the process by which the hysterical condition is induced. He thought the period of treatment in the case reported might perhaps have been materially reduced by suggestive therapeutics.

Dr. Jacobi said that the objection made to the treatment on the score of its time-consuming nature was hardly sufficient to condemn it. She had seen a number of cases that had gone from one physician to another without benefit, although doubtless physicians generally were well acquainted with the principles which should underlie the successful treatment of such cases.

The Morbid Anatomy of a Case of Progressive Muscular Atrophy Which Was Clinically One of Amyotrophic Lateral Sclerosis.—Dr. Carlin Philips read this paper. He said that the patient was a woman of thirty-six who had come under Dr. Collins' observation for the first time on June 17, 1897. She had then complained of severe frontal headache, inability to lift the head from the pillow without the help of the hands, tremulousness of the hands, and easily induced fatigue. She had lost thirty pounds. Examination showed atrophy of the supraspinatus and of the right shoulder girdle, and these muscles showed fibrillary twitchings. The knee-jerks were increased; there was ankle clonus on both sides; there was no affection of the special senses. Six months later she had complained of dyspnea and had shown loss of will power and suicidal impulses, together with some difficulty in swallowing. The atrophy of the muscles was more marked, and extended to the trapezius muscle. She began about this time to have attacks of major hysteria, and the atrophy increased rapidly. The gait became spastic and the body rigid. She had the use of her limbs up to about six weeks before death on May 25, 1899.

Autopsy Findings.—An autopsy was allowed only upon the brain and spinal cord. The weight of the body was forty-eight pounds. The meninges of the brain were anemic. The brain was normal in gross appearance, as was also the spinal cord. The latter was carefully segmented and prepared in various ways for examination. In the second cervical segment was a concentric zone encircling each anterior horn and involving the anterior mesial and anterolateral portions of the fundamental columns, while the tracts of Gowers and the pyramidal tracts were left intact. Corresponding to the degenerated areas in this segment the neurogliar proliferation was very slight. The fourth cervical segment showed a sinking in of the periphery just at the margins of the anterior roots, and this change of contour extended down several segments. The gray matter extended laterally giving a sickle-shape to the degenerated area. While there was no evidence of the destruction of the cells, the most striking feature was the extensive degeneration of these cells. The fifth cervical segment was practically the same as the fourth.

ORIGINAL ARTICLES.

THE CONDITION OF THE KIDNEYS WITH REFERENCE TO THE EMPLOYMENT OF DIURETICS.[1]

BY ARTHUR R. ELLIOTT, M.D.,
OF CHICAGO.

HUCHARD has grouped from various sources the following indications for the employment of diuretics: (1) To maintain the action of the kidneys; (2) to evacuate fluid effusions; (3) to soothe and diminish irritation of the genito-urinary organs; (4) to modify the urine and prevent formation of calculus; (5) to exert a derivative effect through the renal passage; (6) to hasten elimination of toxic substances from the organism.

It may be said that diuretics are of little if any avail in removing inflammatory effusions or procuring absorption of chronic effusions, such as ascites and hydrothorax. Hence the main objects to be attained through their action are the maintenance of renal function, dilution of the urine and removal of edema. Diuretics exert their physiological effect upon the kidneys in several ways. Brunton's simple classification divides them, according to their mode of action, into diuretics which act upon the blood, those which act upon the circulation, and those which act upon the tubules of the kidney. The first of these classes—those which act upon the blood—includes the saline or refrigerant diuretics, chief among which are the vegetable salts of potassium and the salts of lithium, sodium, and strontium. Since the main office of the kidneys is to depurate the blood, we would naturally expect them to be influenced in their function by slight changes in the composition of the blood and such we find to be the case. This fact explains the diuretic action of water and of the class of saline diuretics. It has been shown that the power of these latter bodies to induce urinary secretion is directly proportional to their power of attracting water, and that the result of their presence in the blood is to cause an active flow of water from the tissues into the blood which in this way becomes diluted to an extent varying with the osmotic pressure of the substance introduced. In other words, hydremic plethora is induced with dilatation of the visceral blood-vessels and general rise of blood-pressure with increased rapidity of flow. The diuresis resulting from these substances lasts no longer than the hydremic condition and increased blood-pressure and ceases when only a small amount of the drug has been removed. The fact that the increased urinary flow does not persist until entire excretion of the body is accomplished shows that these substances are not specific stimulants of the renal function, but act indirectly through increasing the volume of the blood and raising vascular tension.

The effect of the second class of diuretics—those which act upon the circulation—is rather more complex, but in the end is much the same as the preceding class. They may be designated the cardio-vascular diuretics and include digitalis, strophanthus, theobromine, convallaria, adonis vernalis, sparteine, caffeine, and the cardiac stimulants generally. Their diuretic effect is accomplished by their influence in producing increased pressure in and flow through the glomerular capillaries.

The action of digitalis may be taken as typical of this class. Digitalis slows and strengthens the cardiac systole and at the same time constricts the arterioles so that blood-pressure is raised thereby relieving venous stasis and bringing about improved circulation through the kidneys. It is, perhaps, the most generally useful diuretic, being especially valuable in dropsy associated with cardio-asystolic conditions. With a normal heart its action upon the kidneys is extremely doubtful. Its effect upon the urinary secretion in health has been carefully studied by numerous observers, but with such diverse results as to render it probable that its diuretic action is in great measure indirect rather than direct.

In connection with the circulatory diuretics may be mentioned the action of the vasodilators. These drugs, principally nitrites and iodides, act by dilating the renal capillaries and so moving more blood into the kidneys. At the same time general blood-pressure is lowered. In this manner diuresis is effected by substituting vasodilation for vasoconstriction, which is the dominating factor of diuretic medication.

Diuretics of the third class act upon the secreting structure of the kidneys so as to increase its function. They are mainly renal irritants, their action upon the kidneys being compared by Brunton to the action of drastic cathartics upon the intestine. In small doses they produce diuresis by stimulation of function, while in large doses they give rise to severe irritation and even inflammation of the kidneys. The most important members of this group are turpentine, juniper, squills, copaiba, cubebs, cantharides. Calomel and blue mass may be mentioned as diuretics which do not belong to any one of the foregoing classes. They are indirectly diuretic, probably through their influence upon the liver resulting in the formation of substances which are diuretic in action. Some of the diuretics pro-

[1] Read at the annual meeting of the Illinois State Medical Society, Peoria, Ill., May 22, 1901.

duce their effect upon the kidneys by acting simultaneously in more than one way. Thus, caffeine, theobromine and squills are at once cardiovascular diuretics and stimulants of the renal epithelium.

The facts passed thus lightly in review regarding the action of these drugs develop the interesting conclusion that only a comparatively few of them are true renal diuretics. It is only in the case of the third class of irritant-epithelial diuretics that the renal function is increased by direct action of the medicament upon the kidneys. All other diuretics exert their effect upon the urine, indirectly through the circulation, either by raising blood-pressure through improved cardiac action, or by inducing a watery condition of the blood with coincident heightening of vascular tension.

In acute irritative and inflammatory conditions of the kidneys, a state of physiological rest is indicated and for this reason drugs directed toward increasing the urinary flow should not act directly upon the kidneys, but indirectly by stimulating cardiac action, raising blood-pressure or producing vasodilation. For this reason the irritant epithelial diuretics should never be employed in inflammatory diseases of the kidneys. It is well known that diuretics often fail of action when their effects are most needed. This is not because they are inconstant in their action, but because of unsurmountable obstacles which frequently are opposed to their action and as well because they are often administered without a proper appreciation of the indications of the particular case. Thus, in cardiac disease, the kidneys may be so engorged as to render secretion impossible and in advanced Bright's disease diuretics may be powerless because of extensive destruction of the secreting cells. It is well to bear in mind that, when the function of the kidneys is impaired, it is prudent to use medicines having toxic properties with extreme caution. This applies to many of the diuretics, especially the cardio-vascular diuretics and calomel. When the impermeability of the organs has advanced to the point where systemic waste and toxins are retained, medicinal substances may also fail of excretion and drug intoxication may be added to uremic poisoning. It should also be remembered that there is a marked antagonism between the function of the bowels, skin and kidneys, so that great activity of one of these emunctories lessens secretion by the others. For this reason, when diuresis is desired, sweating and purging should be avoided. After a diuretic is administered, the patient, as a rule, should be kept cool. A drug administered for diuretic purposes may, if given hot and the patient kept warm, act as a diaphoretic.

Diuretics are employed in functional and organic derangements of the kidneys. In functional urinary disorders they are mainly used to dilute the urine and correct undue acidity and thus soothe and diminish irritation of the urinary passages. To accomplish these results nothing is so well adapted as simple diluents or the class of saline diuretics. There is no doubt that, as a class, Americans do not drink enough water and consequently are liable to concentration and undue acidity of the urine, with irritation of the urinary organs and disposition to the formation of crystalline concretions. We know that organic disease is frequently the result of prolonged functional irritation of an organ.

I have felt satisfied that in a number of my cases of chronic interstitial nephritis in middle-aged subjects the underlying cause has been prolonged irritation of the kidneys from an overacid, concentrated urine, the result of insufficient water-drinking. Herein is one reason for the popularity of the so-called "lithia waters" and, although one may feel some skepticism regarding the efficacy of the lithia they contain, they serve a good purpose by inducing consumption of a water with supposed medicinal properties in cases in which plain unsophisticated water would fail to enlist the patient's interest. At this point a word might properly be spoken in warning of the evils of overconsumption of water in organic kidney disease. It is customary to direct patients with chronic kidney disease to partake freely of water. Unless some limit be placed upon this unquestionably good hygienic measure, the patient may apply himself too freely to the practice, and as a result pass habitually from eighty to one hundred and twenty ounces of urine. The congestion induced in the glomerular circulation by this state of affairs may cause decided harm to the organs. In a number of my cases increase of albuminuria and blood in the urine have resulted.

Whether any of the medicinal diuretics possesses the power of dissolving urinary concretions is doubtful, but there can be no question of the efficacy of freely diluting the urine by means of diluents and diuretics, in preventing their growth and formation, and in relieving the irritation they produce.

In the various forms of nephritis, diuretics are much employed. Before considering their value in this disease, a word might aptly be said in deprecation of the tendency to give diuretics without due reference to the indication of the particular case. Many physicians apparently regard the presence of organic kidney disease as sufficient reason for diuretic medication, and potassium, strontium, digitalis or even the irritant diuretics are administered, often to the distinct detriment of the patient. It is about as reasonable to give diuretics in this indiscriminate manner as it would be to administer cardiac stimulants to all cases of organic heart disease, without reference to the state of the cardiac muscle. Diuretics should only be given in Bright's disease in response to definite indication.

In acute nephritis we have a much more promising field for the employment of these agents than in chronic nephritis. In cases of acute nephritis attended with oliguria and dropsy our endeavor must be to relieve as far as possible all strain upon the engorged capillary system of the

glomeruli, so that the organs may resume their normal function. Any attempt to stimulate renal action and to reduce dropsy during the acute inflammatory stage is apt to meet with disastrous consequences by throwing work on organs incapable of bearing the strain. It is important, however, to maintain the function of the kidneys. Indeed, it becomes a condition of life that quantity of urine should make up for quality. This must be accomplished without imposing any strain upon the diseased organs. During the stage of acute inflammatory engorgement a free urinary flow is best favored by the liberal use of water, either plain or with one of the vegetable salts of potassium, added in sufficient amount to render the urine alkaline. Certain authorities (Ewald, Cantani, Labadie-Lagrade) reject the administration of all diuretics at the commencement of nephritis, but Furbinger, Leyden, Gairdner and others contend that saline diuretics are absolutely harmless even when nephritis is in full swing. I am sure that general experience is in conformity with this latter view. It has been affirmed that the salts of potassium increase uremia, but confirmation from practical experience is lacking on this point. Unfortunately, these drugs may prove very distasteful to the patient and give rise to nausea and vomiting. They should be withheld at the earliest sign of digestive disturbance.

Gerhardt, Coignard and Purdy contend that alkaline urine dissolves the fibrinous exudations which plug the tubules, a contention which has been verified by Cantani. This action is one of the most valuable attributes of the saline diuretics and serves to greatly facilitate the function of the embarrassed kidneys by clearing the tubules of inflammatory products. Sir William Roberts states that in no instance in which the urine had been rendered alkaline during the first week of the complaint had he observed the more severe uremic symptoms and secondary inflammations.

When the oliguria is great and uremia threatening, resort should unhesitatingly be had to the subcutaneous injection of normal saline solution. The solution should be freshly made and freshly sterilized and should be slowly injected at a temperature of 100° F. into the buttock or cellular tissue of the breast. One quart every six to eight hours should be given until the kidneys respond, or instead a pint may be injected every three hours. The immediate effect of the introduction of these large quantities of saline fluid is to relieve vasomotor constriction probably by diluting the toxins in the blood and to stimulate the heart's action, thereby raising general blood-pressure and favoring elimination by the natural channel. I know of no measure so effective in bringing about copious diuresis. The effect upon the kidneys is frequently most remarkable. It may require several infusions to produce any important effect, but when diuresis begins it is often extremely free and lasting. High enemata of hot normal salt solution may be used instead of the subcutaneous injections, but they are not nearly so effective. When the disease has passed into the subacute stage with abated fever and subsidence of the interstitial and parenchymatous inflammation in the kidneys, theobromine may be administered if a diuretic seems indicated and the salines prove ineffectual, or if persistence of edema suggests its dependence upon atony of the cardiac muscle, digitalis may be resorted to.

In chronic renal diseases, the indications for the employment of diuretics are to maintain the urine and thus assist the elimination of urinary and other toxic bodies and to remove edema. In chronic interstitial nephritis polyuria and not oliguria prevails and, consequently, no service can be expected from diuretics, nor is their use at all necessary until the stage of cardiac failure is reached. With dilatation of the heart and lowering of systemic blood-pressure, diminution of urine supervenes and dropsy develops. Appreciation of the fact that dropsy and oliguria are due to the circulatory failure indicates the futility of giving diluent and saline diuretics, or expecting results from any measure not directed toward restoring cardiac action and raising the general blood-pressure. Digitalis is the drug indicated and favorable results upon the urine may be expected from its employment, especially if vasodilators be simultaneously administered to unlock the arterioles and thus neutralize the constricting action of the digitalis. Strophanthus, caffeine, sparteine, convallaria and theobromine may be employed in place of digitalis, but they are much less reliable. When the renal impermeability is advanced, the influence of digitalis and other diuretics is doubtful and we should proceed in their administration with the utmost caution.

In chronic diffuse nephritis the quantity of urine varies inversely as the amount of dropsy. Diminution is the rule, although a considerable temporary rise may be seen during the period of subsidence of the dropsy. Saline diuretics and diluents will consequently serve useful purposes by increasing the urine and flushing the renal tubules. The usefulness of digitalis and the cardio-vascular diuretics will depend upon the condition of the heart and systemic blood-pressure. In the engorged or cyanotic kidney subsequent to serious circulatory derangement, the cardio-vascular diuretics and especially digitalis are the only ones to be considered. It is in these cases that calomel exerts most strikingly its diuretic effects. Digitalis may be given alone, or in combination with squills and blue mass, if the kidneys are free from organic disease. A valuable combination is digitalis and bitartrate of potassium, as is also digitalis, strophanthus and acetate of potassium.

Finally, regarding the usefulness of diuretics in renal dropsy. The factors entering into the production of renal dropsy are both circulatory and hematic. The circulatory condition probably consists in undue permeability of the capillary wall, allowing the outpouring of large quantities of fluid into the lymph-spaces. The capillaries, although not muscular, have been shown to be

contractile and it may be presumed that they offer increased resistance to blood abnormal in character from the presence of toxin which the diseased kidneys fail to excrete. This involves increased intracapillary pressure and with it must be associated some change in the capillary walls which renders them unnaturally permeable. With these changes in the vessel-walls is associated a true hydremic plethora of the blood. Not only is the blood poor in solids, but the volume of the fluid is increased. These factors operating together cause the dropsy of acute renal disease. Their primary cause is undoubtedly the toxemia due to the kidney lesion. Notwithstanding the fact that the flow of urine varies inversely with the amount of dropsy, the oliguria is probably a result rather than a cause of the dropsy. This view of the production of dropsy does not hold forth a very hopeful prospect to the administration of diuretics. In fact, the action of these agents in renal dropsy is very uncertain, owing, no doubt, to the different conditions accompanying acute and chronic renal disease. Dropsy in acute nephritis is usually of purely renal origin and consequently is very little amenable to favorable influence by diuretics.

In chronic nephritis the problem is essentially different. The increased capillary resistance just referred to, which is produced by the presence of toxins in the blood, involves increase of arterial tension and of cardiac effort to overcome peripheral obstruction. When renal disease is of very gradual development, as in many cases of chronic interstitial nephritis, and the heart has been allowed time to hypertrophy, gradually, with the rise of tension, dropsy is postponed or may be altogether absent. If the patient survives to the last stages of the disease, the cardiac compensation gives way and dilatation with mitral insufficiency supervenes. Under such circumstances dropsy develops and may be regarded as more cardiac than renal. As dropsy of cardiac origin is much more easily influenced than that due to purely renal causes, a better field exists for the employment of diuretics, especially the cardio-vascular diuretics in the dropsy of chronic nephritis than in the acute disease. The latter form of dropsy must be combated by measures directed toward the promotion of excretion by other channels, especially the skin and bowels.

Conclusions.

1. Except in the case of the irritant-epithelial diuretics (turpentine, cantharides, etc.) the entire class of diuretics may be said to exert their effect upon the urine by acting indirectly through the circulation.

2. Owing to the necessity for sparing the kidneys all irritation, drugs given for diuretic purposes should act indirectly rather than directly, consequently the secretory diuretics are contraindicated in irritative and inflammatory renal conditions.

3. In functional urinary disorders diuretics are mainly useful to overcome concentration and hyperacidity of the urine. To accomplish this, simple diluents and salines are best adapted.

4. In acute nephritis saline diuretics are permissible throughout the entire course of the disease and exert a beneficial influence by increasing elimination and clearing the tubules of inflammatory débris. Subcutaneous saline infusion constitutes our most powerful eliminant in desperate cases.

5. In chronic nephritis the cardio-vascular diuretics are most useful, owing to the fact that oliguria and dropsy are usually the result of circulatory failure. The dropsy under such circumstances, being of cardiac origin, may be benefited by cardio-vascular stimulants provided the kidneys are not too badly damaged.

6. Dropsy of purely renal origin is not amenable to favorable influence by diuretics.

7. Although the morbid process in the kidneys may furnish us with our primary inspiration to diuretic medication, it is the condition of the heart and circulatory apparatus in most cases that determines the choice of an agent.

THE THERAPEUTICS OF SUBACUTE AND CHRONIC HEART DISEASES.[1]

BY THOMAS SATTERTHWAITE, M.D.,
OF NEW YORK.

NOTWITHSTANDING all of the recent advances in cardiac therapeutics (and the changes of the last ten years have been revolutionary), we are less and less disposed to advocate special remedies for special affections. This is particularly true when the valves are at fault, for we have learned to put less weight on abnormal sounds and more on attendant phenomena, and especially on the character of the tissues about the valves. A few statements that I believe will be admitted without controversy by those who have made a study of heart diseases will serve to illustrate my meaning.

The gravity of a valve lesion is not always measured by the intensity of its murmur. A loud and harsh murmur is not incompatible with an average length of life; whereas a valve may be almost occluded as in mitral stenosis, without giving any recognizable auscultatory sign.

A loud murmur in recent endocarditis may mask an older and much more serious lesion, simply because in one the edges of the valve are smooth, and in the other, rough. The maximum intensity of a murmur is not always best heard over the area that our text-books designate as the proper point for auscultation, for an aortic direct murmur can sometimes be best heard over the pulmonary area, an aortic regurgitant murmur, over the mitral area.

Single valve lesions are the exception not the rule.

With the best opportunities and the largest experience one may not always be able to distin-

[1] Read at the Annual Meeting of the American Therapeutic Society, Washington, May 8, 1901.

guish between a functional and an organic murmur. Obstruction of any valve is usually associated with insufficiency.

Now, facts like these are plainly bars to a correct diagnosis derived from purely auscultatory signs; and from our present view they appear to be insuperable. As a result, the clinician of to-day realizes limitations in the value of purely auscultatory signs, and only utilizes them in connection with other signs. And so if he recognizes aortic obstruction, and does not note insufficiency, he still mentally adds to his diagnosis a probable insufficiency, because the two usually coexist; certainly if the obstruction has reached an advanced stage there is almost inevitably regurgitation. But even if the physician has abundant opportunities and the requisite experience he may still sometimes fail to locate an affected valve. A few figures will illustrate this point.

In 46 cases of mitral insufficiency from my hospital postmortem records 34, or 75 per cent., were correctly determined during life, though in 39, or 86 per cent. of them, other valve lesions were present to complicate matters. An accuracy of 75 per cent. is a creditable showing. In sharp contrast, however, is the record in mitral stenosis. From 27 cases the following results were obtained: The lesion was not noted at all in 19, or 70 per cent.; the signs were not heard or misinterpreted in 4, or 15 per cent.; the signs were heard and correctly interpreted in 4, or only 15 per cent. In 18 or 66 per cent. of these cases of stenosis there was insufficiency.

These figures certainly indicate, as I have said, that in the majority of instances a single valve lesion is complicated with one or more; and therefore therapeutics founded on the action of a drug in a supposed case of pure mitral stenosis or pure aortic insufficiency, for example, are illusory, in that we are probably not dealing with a single lesion, but with two or more. One should, therefore, be skeptical when he reads that a remedy is adopted for mitral stenosis, but not for mitral insufficiency. In fact, it is a matter of minor consequence, so far as treatment is concerned. what the precise valve lesion is, while it is vitally important to determine whether the disease is acute or not, the heart hypertrophied or dilated, the character of the pulse, and attendant symptoms relative to implication of other organs.

And yet such ideas as this are prevalent, that, with a pulse of say 50 or 120, the rate must be brought to a given standard; or so long as we hear a loud murmur or find an intermittent pulse, the heart must be at once stimulated with cardiac drugs, and in many cases the unfortunate patient is subjected to a course of drugging that is useless if not harmful.

Let us note here that the newer methods of treatment consist in rest, alternating with bodily activity; determination of the blood to the periphery rather than venesection; a carefully regulated diet, with stomachics if necessary. In place of the so-called heart-tonics or stimulants which we now employ, systemic invigorants or alteratives, with or without mild cardiac sedatives, should be given, reserving the so-called cardiac or circulatory stimulants and hydragogue cathartics for emergencies which may arise from complications, such as pneumonia, advanced Bright's disease, diabetes or abdominal dropsy, where we either have abandoned hope or are merely aiming to sustain life (as in lobar pneumonia) during a brief period of cardiac strain. Of course, I do not desire to disparage rest. It has its value for every wearied organ, but complete rest from all bodily or mental activity has a limited value in the treatment of heart diseases and is applicable, only in cases of acute dilatation, with or without endo- or pericarditis, in some perenchymatous affections, or in the last stages of chronic heart disease. In fact, as soon as the immediate danger from any serious heart disturbance is over, active or passive bodily movements should be inaugurated, for enforced rest superinduces degenerative processes and retards the physiological activities necessary to rid the system of effete material.

It seems almost absurd to discuss the matter of venesection in heart disease, for it is hardly known in our latitude; yet it is recommended in two prominent American text-books which have appeared within the past ten years. In a practice of more than thirty years I do not remember ever to have known of its use in heart cases, although I have venesected for the vertigo of plethoric people, in cerebral congestion and in orchitis, and have quite often used wet cups in the sthenic pneumonia of robust young people, and have had no occasion to regret the practice. But in cardiac cases, local derivation by dry cups, frequently resorted to, fulfils all the indications, when we are aiming to relieve the right heart. In chronic pulmonary engorgement, however, carbonated baths and resistant exercises do the work best by determining the blood from the internal viscera to the muscles and integument.

So much for intracardiac pressure. Diminution in the extracardiac pressure, another important matter, is also accomplished in some instances by remedies that are mild but effective. A restricted diet in which the ordinary amount of nitrogenous food is somewhat increased and the carbohydrates decreased, lessens fermentation and so diminishes gaseous distention of the stomach, thus preventing this form of pressure on a distended heart. Inasmuch, however, as the carbohydrates supply energy to the system they should not be forbidden altogether. In delicate cases the use of malted foods containing predigested starch is helpful. It is apparent, therefore, that a mixed diet is preferable. In the matter of fluids, inasmuch as lithemia is at the back of most chronic heart diseases, they should be used freely as solvents for uric acid, if not for any

other purpose, and, as most of these patients lead somewhat sedentary lives and suffer from indigestion, we cannot overlook stimulants and antifermentatives for the gastro-intestinal tract.

I do not propose to discuss here the carbonated-bath systems, and the associated resistant exercises more than to say that I cannot well see how the present method of generating carbonic-acid gas by the acid sulphate of soda and bicarbonate of soda, or allied methods, admits of much improvement. The use of liquid carbonic acid is attended with such difficulties that I and some of my colleagues, who make use of carbonic-acid gas in various ways, have abandoned it. If, as I believe, it takes forty-five minutes to carbonate a tubful of water at 40° F., it would naturally take longer to carbonate it at 97° F. or 98° F., the heat required for the initial bath, and even if so charged the water would not retain its original gas-percentage. On the other hand, by the use of the carbonating powders and discs there is a constant evolution of nascent gas which has more nearly the properties of the Nauheim Spring waters and is more efficient than stored gas, for it is in a state of more minute division and besides the percentage remains about the same during the evolution. Actual experience confirms this statement. Moreover, there is always the danger of explosion when liquid gas is used, for this is always possible so long as there is a pressure of 1,000 lbs. to the square inch in the drum or apparatus and the attendant is inexperienced or careless.

Although the uses of the carbonated bath and resistant exercises are finding a constantly increasing field of usefulness, it is in cardiac insufficiency that they have a special field. In fact, they are applicable to all classes of heart weakness, whether resulting from acute infections, such as diphtheria, typhoid and the acute exanthemata, mineral poisons, dyscrasiæ, like lithemia and diabetes, or organic diseases of the heart and vessels. They are also useful in cardiac neuroses, such as are produced by emotional causes, hysteria, the tobacco vice, tea or coffee poisoning and masturbation, in functional diseases of the heart, such as are seen in anemia and in overuse of drugs, such as digitalis, strophanthus and others of this group, thyroid extract, or violent reduction methods, such as are practised at Carlsbad, Kissingen and other German spas. Usually angina pectoris, diabetes, parenchymatous nephritis, arteriosclerosis and phthisis are regarded as contra-indicating carbonated baths and exercises and my experience during the last year in general sustains this view, although it also indicates that in some instances they may be resorted to with benefit. However, we are making history as to the utility of baths and exercises in angina, arteriosclerosis, glycosuria and albuminuria, as the following cases show.

Case I.—Angina pectoris; direct aortic murmur; cyanosis; flatulent dyspepsia; general superficial edema. A young married woman of fine physique, weighing 140 pounds, was referred to me by Dr. F. A. Burrall of this city in May last. She had been ill for five or six years, and for the last eight months had been under active treatment for her heart affection, although gradually growing worse. Previous to her illness she had been given to athletic sports, such as riding, swimming, etc. The attacks of angina were regarded by her physician as of the true variety. The precordial pain was described as of "a house resting on the chest." Flatulent dyspepsia, dyspnea and transient cyanosis were other symptoms given. Attacks were brought on by nervous strain of any kind, particularly by prolonged conversation. They were temporarily relieved by nitroglycerin.

On physical examination the pulse was found to be 80, soft and weak, but without intermission. No impulse at the apex, but burning pain. No thrill; precordium and sternum sensitive to the touch and swollen; cording of lymphatics under left breast; apex over sixth rib and ⅛ inch inside of mammilla and 2⅜ inches below intermammillary line; at apex slight systolic murmur. At base systolic murmur carried well up into the great vessels.

Potassium citrate, nitroglycerin, strophanthus and strychnine had been given. All medicine was stopped and camphor monobromate in 2-grain doses ordered, with carbonated baths, and resistant exercises and massage. After four days of this treatment the swelling of the breasts had disappeared and after a course of only fifteen days she was sufficiently improved to return home, and in the following September she was enjoying life, camping in the Maine woods, and feeling, as she expressed it, "restored to health." On the other hand, a patient with arteriosclerosis, angina, and complications, did not do so well.

Case II.—Angina pectoris; arteriosclerosis; glycosuria; albuminuria; apoplexy. Mr. H., a retired merchant, seventy-four years old, of full habit and rather obese, was sent me in September, 1889, by Dr. H. V. Barclay. He had been complaining of dysphagia and obscure gastric attacks coming on at night. On physical examination his pulse was found to be 80 and feeble, with hard radials, rolling under the fingers. Respiration 24. Impulse at apex hard to detect. Apex ½ inch outside of the nipple, and ½ in. below the intermammillary line. Heart sounds indistinct. Urine 1¼ per cent. sugar. Traces of albumin; specific gravity 1015.

Owing to his feeble condition the baths and exercises were stopped on the thirteenth day of treatment. On this day he had a gastric crisis at night and his head was confused in the morning. The condition of the urine remained the same. On October 23d a musical

murmur was heard with systole at the apex. He was now put on potassium iodide. Two or three attacks of angina had been brought on by the smell of cooking, and others by gastric or intestinal distention. On October 27th an attack was induced in my office by a smell of fresh paint. Relief was always obtained by capsules of nitrite of amyl with nitroglycerin, etc., the formula of which is given later. Patient nervous and hysterical. From October 30th for three weeks he was free from attacks, using the capsules only to ward off attacks, but his diet was strict. Under the iodide of sodium increased to nine minims of the saturated solution three times a day, the patient continued to improve, although he had occasional attacks of dizziness and was troubled by a sound like that of running water in his right ear, indicating the gravity of the disease in his cerebral arteries. In December he passed from under my care and on February 15th died of an apoplectic attack. It is scarcely astonishing that baths and exercises should have done so little in this case, where there was such a complication of disorders. It is important, however, to know they did no harm, notwithstanding the elements of albuminuria and glycosuria. In fact, I have not found that mild albuminuria and glycosuria necessarily contraindicate the use of baths and exercises as the following case will show.

Case III.—Arteriosclerosis, aortic direct and regurgitant murmur; cardiac hypertrophy albuminuria; glycosuria. L., sixty-four years of age, a retired man of business, was sent me by Dr. D. Bryson Delavan of this city, on account of persistent epistaxis due to endarteritis. Patient stated that he was rather short-winded, had occasional fainting attacks and shooting pains over the heart. No headache but pain in back of neck. Pulse 80, intermittent. Respiration 16. No dyspepsia. Facies arteriosclerotica. Physical examination, superficial enlargement of veins of chest especially of precordial area. Loud systolic murmur with first sound propagated up the great vessels and with second sound radiating to the right and also down the sternum. No mitral murmur. Heaving impulse. The apex was found just within the nipple and 2 inches below the intermammillary line. The loud murmur with the first sound at base corresponded with an area 5 inches in diameter, extending 3½ inches to the right of the median line and 2 inches to the left of it. By fluoroscopy this area threw a somewhat dark shadow, and to my mind indicated a fusiform dilatation of the aorta (ascending portion of the arch), although the shadow was not as dark as I have seen it in sacculated aneurism. Examination of the blood showed hemoglobin, 95 per cent. Examination of the urine was as follows: Daily amount, 24 ounces; specific gravity, 1025; traces of albumin; sugar, 2 per cent.; hyaline casts; urea, 6 grains per ounce. The patient took a course of resistant baths and exercises at Nauheim. On his return he was no longer short-winded, but had shooting pains occasionally over the heart. Pulse 72, one intermission instead of 4 per minute. Respiration 16. Superficial veins of chest not so prominent. Murmur the same, but cardiac enlargement diminished. As the patient contracted a rheumatic attack on his return voyage, he was put on the hot-air treatment and the iodides were given.

January 2, 1901, examination of the urine was as follows: Specific gravity, 1015; amount, 33 ounces; no albumin; no sugar; traces of indican. On March 23, 1901, the patient expressed himself as free from all disagreeable symptoms, although the auscultatory signs were little changed. The patient is now attending regularly to business.

There is also a condition that has been called idiopathic dilatation of the heart, such as is seen in young boys and especially girls, often of the working class, and those that are anemic and neurotic. It is seen also in phthisis or in any debilitating disease. The signs are an enlarged cardiac area, feebleness or absence or diffuseness of impulse, faintness of first sound at apex with accentuation of the second pulmonary sound, and marked accentuation of the aortic second sound (the hyperdiastole of Rosenbach). It is apt to be associated with menstrual disturbances, constipation and flatulence and is improved by rest, massage, tonics and laxatives and a restricted diet. If any cardiac stimulant is required, in the absence of the baths and exercises, iron and strychnine, but not digitalis or drugs of this group, are indicated.

In cases of kidney trouble it is not always well to be too certain about the result. As I have shown, mild cases of diabetes and albuminuria may be greatly benefited. In fact I have seen no harm but only benefit in glycosuria up to 2½ per cent. sugar. In severe cases, however, the diabetes should be treated successfully before baths are given.

Although slight albuminuria is no bar to baths and exercises, in parenchymatous nephritis the matter is different, as shown by the following case.

Case IV.—Cardiac hypertrophy; mitral disease; abdominal dropsy; chronic nephritis. Mrs. ——, twenty-nine years of age, from Memphis, Tenn., was referred to me by Dr. E. Miles Willett of Louisville, Kentucky, in October, 1889, the patient being extremely anxious to try a course of baths and exercises. She was unable to walk when brought to New York, and for several days after her arrival was confined to her bed. At fourteen years of age she had inflammatory rheumatism and at seventeen typhoid fever. In 1897 she had a hard labor, was cyanotic so that no anesthetic was given, and her child was delivered with forceps.

On examination a harsh systolic murmur was heard at the apex and carried round to the back. Apex below the left border of the nipple. Pulse, 64. Temperature, 98° F. Respiration, 24. Urine, specific gravity, 1012; scanty, faint trace of albumin. She was taking codeine in ½-grain doses, which had been given her in alternation with digitalis.

These drugs were stopped and she was put on strychnine and caffeine in small doses, with calomel as a laxative. Inasmuch, however, as the amount of albumin was small and the casts were infrequent, the patient was put on carbonated baths and exercises, although they were given irregularly, as attacks of heart failure and partial suppression made it necessary to proceed cautiously with them. However, after thirteen baths had been given, it became apparent that the patient had a confirmed chronic parenchymatous nephritis, and that, therefore, the baths would be of no use and might do harm. In fact, on one occasion the albumin during an attack of temporary suppression reached 66 per cent. by volume. In other respects, however, there was improvement. The patient was at one time able to sit up for a considerable part of the day and had even walked out on the street; the volume of the heart also had diminished, the apex receding ¾ inch toward the median line. On November 10th, however, she was taken down with an acute attack of lobar pneumonia which lasted nine days and during that time it was necessary to administer digitalis to promote the flow of water and relieve the abdominal dropsy that supervened. On four distinct occasions, also, she had attacks of heart failure, the radial pulse on one of them suddenly falling to 38 and three times to 44, during which nitroglycerin, the nitrite of amyl and alcoholics were satisfactorily used to restore the circulation. On November 24th she returned home in an improved condition, though ultimate recovery manifestly was impossible. In fact any improvement in such a case of heart disease complicated with chronic parenchymatous nephritis can of course be only temporary. Death occurred some months later.

Cases of advanced phthisis should never try the baths. I saw such a case with Dr. J. H. Huddleston of this city in February, 1900.

Case V.—Phthisis; mitral stenosis. The patient, a man who had been in very active business had long suffered from heart trouble, but had not been seriously ill until six months previous. He had been seen by a prominent consultant who diagnosticated the case as a chronic pneumonia of heart disease. I found him emaciated and bathed in a cold, clammy sweat. Radial pulse, 37 to 44, very intermittent and irregular in force. There had been hemoptysis, but no evening rise of temperature had been noted. Urine, 20 to 30 ounces; albuminuria. Feet and abdomen had been dropsical sometime previously. No bacilli.

Physical examination showed the apex in the sixth space. Action of heart tumultuous. Blowing murmur over the mitral area, not transmitted. Dulness at left apex. Cavernous respiration. I made the diagnosis of phthisis, notwithstanding the negative report as to bacilli in the sputum, and refused to recommend baths or exercises. In the following summer contrary to my repeated advice and that of his medical attendant, although his condition was much improved, he went to Nauheim where my diagnosis was confirmed, and after treatment by baths and exercises he was ordered to Egypt for the winter. He did not reach Egypt, however, but died at Rome within a year.

Cases of phthisis with albuminuria and hemorrhages should not take baths and exercises, at least until the pulmonary and renal symptoms have been successfully treated, or at least held in check.

In the subacute dilatation of young people, especially in anemic or neurotic girls and boys who lead a sedentary life, a little more exercise of a quiet nature in the open air, with nutrients, like malt, iron, arsenic and strychnine, and carbonted baths and exercises tend to restore the heart's tone and diminished dilatation.

In older people strychnine in doses from $^1/_{60}$ to $^1/_{30}$ grain every four hours is a good all-round nerve tonic. It stimulates the nerve centers in the medulla and spine and overcomes functional debility, whether of nervous of muscular origin. But it is seldom necessary to give more than $^1/_{40}$ grain at a dose. In fact strychnine, I hold, should not be kept up more than a week or ten days at a time, because it is cumulative and apt to disarrange digestion. Besides it conteracts both heart and arterioles, so that it is evidently undesirable and even dangerous for continuous use or in large doses. Somewhat similar in action is arsenic, a general tonic suited especially for the debility of anemic persons or of old age. A good plan is to combine arsenic, $^1/_{10}$ grain, with iron. Under the same category comes the cactus or *cereus grandiflorus* (night-blooming cereus of Mexico). It seems to stimulate the vasomotor centers and so regulates the heart. I have found it useful in myocardial diseases. It appears to have no cumulative effects. The dose is one to two minims of the fluid extract. It is better borne than digitalis or strophanthus. It acts probably as a general nerve tonic and appears to be a good succedaneum for strychnine.

Laxatives are essential in the treatment of chronic heart diseases. They should be carried to the point of producing at least one liquid or semi-solid movement a day. For this purpose I have been in the habit of using waters that contain sulphate of soda, such as the Apenta. In place of them I now use a preparation made for me by H. A. Cassebeer to get

the effect of the diuretic, hepatic and saline aperient. It consists of equal parts of the sulphate of soda, phosphate of soda and the neutral tartrate of potassium. The dose is one to two drams dissolved in hot water and it is taken warm one hour before breakfast. It may be replaced by a hepatic such as I prescribe frequently. It is composed of resin, podophyllin, gr. ½; ext. colocynth co., gr. i; ext. hyoscyami, gr. i, and ext. nucis vom., gr. ⅙. One pill may be taken as often as every other night. It can be taken almost indefinitely.

Among the cardiac sedatives I use valerian and also the bromide of zinc, the latter in $^1/_{10}$-grain doses. In bad cases I prefer the tincture of aconite in 2-minim doses every three or four hours. Aconite acts in general as a mild depressant of the heart and pulse. It is a vasomotor dilator, a diuretic to some extent and a mild diaphoretic. It is also very useful in the tumultuous heart, and being a vasodilator it is useful after overdosing with digitalis and drugs that contract the heart muscle. An excellent agent to quiet the mildly neurotic heart is camphor monobromate in 2-minim doses. It is especially useful in the fluttering heart of emotional women. Another drug which has a more limited use is belladonna, is beneficial where there are palpitation, anginoid attacks and arhythmia, but I prefer it as an external application.

For severe attacks of dyspnea, I give nitroglycerin in doses of from $^1/_{150}$ to $^1/_{50}$ of a grain, and I have given the latter dose as often as every hour for many hours together, for nitroglycerin, while it contracts the heart, dilates the arterioles. In fact, I always now use the nitrites for cyanosis or dyspnea in place of digitalis. I have not used erythrol-tetra-nitrate on account of its explosive qualities.

For sudden and violent attacks of dyspnea or angina, whether mild or severe, I give capsules containing each $^1/_{100}$ of a grain of nitroglycerin, ¼ of a grain of amyl nitrite and $^1/_{50}$ of a grain of menthol, with $^1/_{100}$ of a grain of oleoresin of capsicum. These ingredients are suspended in ten minims of castor oil. Relief is usually obtained in less than a minute, often in a few seconds. The capsule may then be given safely at intervals of four hours for days together to prevent subsequent attacks.

In precordial pains and insomonia, especially in the morphine habit, I have used paraldehyde with success. It is a hypnotic, antispasmodic and stimulant. I give it in 30-grain doses, with success, and without any subsequent bad effects. I have also used trional successfully in some instances when there is the opium habit, but I give them only for very brief periods. I never use any preparation of opium except when the patient has the opium habit, which is not uncommon in old cases. One of the most unfortunate results of drugging by digitalis and its allies is that it produces such distressing effects that patients seek relief by opiates. A course of baths and exercises is in these cases a revelation to the patient, who suddenly finds that he can do without either drug.

Digitalis, as is well known, derives its strength and utility from certain glucosides, such as digitalin and its congeners and digitoxin, which regulate the action of the heart and have their most satisfactory field in insufficiency of the left heart. They are inapplicable in an attack of engorgement of the right ventricle, because they do not act quickly enough, so that if there is a heaving impulse, distended jugulars and cyanosis, the indication is rather letting of blood by wet cups.

As a rule, however, I use digitalis only when special complications arise, namely, when we are confronted with urinary suppression or its attendants or sequellæ. It is then desirable chiefly for its diuretic effects. The more I see of heart diseases the more I am convinced that digitalis is uncertain and, therefore, a dangerous remedy in so far as its action on the heart is concerned. It produces spasms of both heart and vessels. In some instances, as in the fatty heart, I believe it may easily cause death in this way. It is truly a two-edged sword, and even in our efforts to get its diuretic effects in suppression, we may cause fatal contraction of the heart. But digitalis is too slow in its action to be relied upon in emergency where diuresis is needed.

In these instances it may be better to use every other means of restoring the action of the kidneys rather than to run the risk of bringing in a fatal cardiac contraction, or, if digitalis is given to secure diuresis, it may be given in small doses every four hours combined with a bitartrate (20 grains). There has been some discussion recently as to the value of digitoxin. It has been claimed to be one of the most active glucosides contained in the *digitalis purpurea*, and has been vaunted as less liable to affect the stomach than digitalin. Its action, however, may be deferred for twenty-four hours, less often for twelve. It is said to be a good diuretic and this characteristic lasts eight or ten days. It will be remembered, however, that Arnold and H. C. Wood (*Amer. Jour. Med. Sciences*, August, 1900) reached the following conclusions from the experiments as to the use of digitalin and digitoxin: Digitalin is a stable compound, etc., while digitoxin is not to be recommended for human medication on account of its irritant action on the stomach when given by the mouth, and because it causes abscesses when given hypodermically, or because it is insoluble and hence is slowly absorbed, making its action irregular. It has also a marked cumulative action. In using digitalis I have latterly confined myself to Merck's digitalin.

Strophanthus is the succedaneum for digi-

talis, but the two have somewhat similar physiological effects. According to Fraser, as a heart compressor it acts much more powerfully than digitalin, and as an arterial depressor much less so. It slows the heart beats, shortening the systole but lengthen the diastole, though unlike digitalis it is not much of a diuretic and does not directly contract the arteries and is not cumulative; in these two last respects it differs widely from digitalis. Unfortunately, in large doses it is apt to produce diarrhea, dyspnea, nervous irritability and cyanosis. It sometimes does well, however, in emergencies, acting more promptly than digitalis, but it is irregular in its actions and its effects are short-lived. It should not be long continued.

Convallaria majalis, the lily of the valley, has much the same physiological action as digitalis. It slows the heart without weakening its tone, and is a diuretic without cumulative action. But in small doses it is an emetic, and it purges actively like jalap or scammony. It is good in dropsies, but inapplicable in mild forms of cardiac disease. It is useful when cardiac stimulation is to be combined with mild diuresis and catharsis. I cannot say that I have ever been much pleased with it.

In adonis, from the *adonis vernalis* and *adonis æstivalis,* we have a drug that owes its properties to a glucoside adonidin whose physiological characteristics are allied to those of digitalis. It slows the heart, regulates it and increases its force and is also a diuretic. It is useless in functional disorders. I have used it, but not in sufficient quantities to be able to speak intelligently of its action.

Sparteine increases the blood-pressure and slows the heart, but it is unreliable, although it may act in twenty minutes or again not for four or five hours. It acts chiefly on the heart muscle, which causes the increased pressure, but it may act also on the vasomotor system. I have had some good though temporary results from it as a diuretic and heart stimulant in doses of $^1/_{20}$ to $^1/_{10}$ grain.

Diuretin, the sodium salicylate of theobromine, is something of a diuretic, though thus far I have not been pleased with its action in cardiac dropsy.

It is well to remember that caffeine is not always made from coffee, but from tea, Paraguay tea, guarana, or the kola-nut; that in large doses or in certain individuals it may produce cardiac spasm and even paralysis, and that its secondary effect on the heart is depressing. Further its action in contracting the vessels tends to congestion, especially of the portal system. The stimulation of the brain and nerves, moreover, produced by caffeine is followed by relaxation. In association with its stimulating action on the heart and vessels, there is a diuretic action when the drug has been administered continuously. Coffee in a certain percentage of cases is a poison. It is not, therefore, always a safe remedy. Usually it is a feeble diuretic, though at times it is effective when other diuretics have failed. I am using it less and less. An error is often made in prescribing citrate of caffeine on the supposition that it has the strength of caffeine. As a matter of fact it contains only 50 per cent. of caffeine.

I must not fail in closing to mention that in place of the hot-air box, used so extensively for diaphoresis in the fatty heart of obesity, rapid reduction in weight may be effected by the use of what is known in England as the "radiant heat" method. The patient lies or sits in a box where the heat is supplied from specially devised electric lamps of large size. This plan is in use in Bath and Leamington (England) and in Carlsbad. It is claimed that heat generated by electricity (radiant) is for some reason more effective in rapid reduction than any other form of heat and peculiarly suited to obstinate cases. My friend Dr. Olive of Leamington, in one case of excessive obesity found it very effective.

In cardiac dropsy, to secure free diaphoresis, I use the muriate of pilocarpine, giving a grain or so a day in divided doses with cardiac and alcoholic stimulants. In fact I have given 1⅗ grains a day, because it requires this amount to secure diaphoresis. Though its action has to be carefully watched by the nurse or physician, I have not had any unfavorable experience with it.

In conclusion, the purpose of this paper will not have been accomplished unless I have made it appear that the idea of complete rest has been surplanted by rest alternating with bodily activity; venesection by determination of the blood to the surface through resistant exercises and carbonated baths; hydrogogue cathartics have been replaced by stomachics and mild laxatives and diuretics; heart stimulants by general nerve stimulants or sedatives, and nutrients, while drugs of the digitalis group are utilized chiefly for their diuretic action in renal complications, mainly parenchymatous nephritis or abdominal dropsy. Drugs of the digitalis group, including strophanthus, convallaria and adonis are always uncertain and, therefore, always dangerous, and should only be employed either when other remedies are inadvisable or in kidney or liver complications, or where we are merely endeavoring to prolong life.

GOUTY AFFECTIONS OF THE KIDNEYS.[1]

BY RICHARD K. MACALESTER, M.D.,
OF GLENWOOD SPRINGS, COLO.

Etiology.—The association of gout and diseases of the kidneys is so frequent that some of the most experienced observers maintain that these organs are rarely found in a healthy or adequate condi-

[1] Read in the symposium on Diseases of the Kidneys at the recent annual meeting of the Colorado State Medical Society.

tion after gout has become fully established. Statistics compiled by Luff of the autopsies of 77 cases of granular kidney disease show uratic deposit in 41, whereas in those described as markedly, or typical granular kidneys, the proportion is 26 to 20. Furthermore, the close relationship between gout and renal disease is amply demonstrated by the well-recognized fact that certain toxic agents, such as lead and alcohol, are productive of both disorders. But, notwithstanding our recognition of the frequent co-existence of the two diseases, and the unrelenting labor of many eminent investigators, the much mooted question as to whether gout is the primary causative factor of kidney trouble, or *vice versa,* is still a matter of controversy.

The rôle of uric acid in the etiology of renal disease, as also in other conditions, is a most perplexing problem. By some observers it is assumed that uric acid and its compounds, acting as a chemical irritant circulating in the blood, set up a destructive process, starting in the epithelium of the convoluted tubes. On the other hand, it has been shown that uric acid is present in the blood only as the soluble sodium quadriurate, an inert non-toxic compound, and it is only under abnormal conditions that it deposits in various parts of the body in the form of the neutral biurate and becomes an irritant. Finally, uric acid may be present in the blood in large quantities, as, for instance, in leucocythemia, but is rapidly excreted without causing any damage as long as the kidneys are in normal condition. It is claimed that only when the functions of these organs are primarily impaired is there deficient elimination of uric acid with all its evil consequences.

Symptomatology.—The clinical symptoms comprise secondary disorders, resulting from renal insufficiency, and differ in no way from those of other forms of chronic interstitial nephritis except for the co-existence of gouty manifestations. As these last named begin to become more chronic, it is not uncommon to find the urine increased in quantity, of low specific gravity, 1006 to 1015, with a deficient amount of urea and uric acid and a small quantity of albumin; microscopically, there are usually few epithelial or granular casts present. Concurrent with these urinary changes are cardiovascular alterations, evinced by hypertrophy of the left ventricle and sclerosis of the arterial system, the arteries becoming hardened and tortuous, and the pulse of high tension.

The course is usually that of the extremely chronic type of Bright's disease, extending often over many years. At first the gouty symptoms preponderate in the clinical picture; later these subside to a great extent and, as the renal trouble progresses, the patient feels relieved of his gout, but finally succumbs to exhaustion, general dropsy, or uremia.

In a goodly number of urinary analyses of gouty patients made by me during the past three years, the above enumerated findings have sometimes been obtained, but by no means in the majority of cases, even in which gout has become eminently chronic, does the urine reveal the co-existence of kidney disease. But common to all cases of gout, as well as lithemia, its next-door neighbor, my quantitative urinanalyses show without exception, a marked diminution in the daily amount of urea excreted quite independent of the slightest evidence, either chemical or microscopical, of a co-existing renal lesion. I report this observation here, being unable to find in the literature, notwithstanding an extended search, any record of this deficient urea excretion, except in conjunction with Bright's disease and general marasmic condition, and I hope to be able to collect sufficient material to present more conclusive results in a future communication.

Pathology.—The so-called gouty kidney is identical in appearance with the small, red, granular kidney of other origin. It is much contracted, with a shriveled granular surface, and the capsules thickened and adherent. The decrease of size is chiefly at the expense of the cortical portion. Microscopically, there are present the signs of destruction of the renal parenchyma with connective tissue formation, degeneration of the epithelium of the uriniferous tubules and the glomeruli, and endarteritis obliterans of the larger arteries. Deposits of uric acid and urates, appearing as white streaks in the direction of the tubes in the pyramidal portion and little white points in the cortical, were attributed to the gouty origin of the trouble, but since these same concretions have been demonstrated in the kidneys of very young children, and in other conditions, they cannot be considered pathognomonic. Besides the small contracted kidney, large, and mixed granular forms have also occasionally been met with, and described as dependent on gout.

Treatment.—There being no specific for Bright's disease, we are compelled to have recourse to symptomatic treatment, dietetics, régime and climate. These vary but little in the different forms of chronic nephritis, and have been thoroughly discussed in other papers. Moreover, broadly speaking, when kidney disease and gout co-exist a course of treatment, proving beneficial to the one, agrees admirably well with the other.

My experience in the treatment of these troubles with mineral water baths has been so encouraging as to induce me to allude to the balneological aspect in this place. We have in Glenwood Springs an unique establishment, known as the Natural Vapor Caves. Thermal springs, boiling up in these, charge the space with vapor and gases and raise the temperature to 110° to 112° F. A few minutes' stay in this atmosphere suffices to set up an intense cutaneous reaction, perspiration continuing, if not checked, for several hours after leaving. The other varieties of baths, though acting in general in a lesser degree of intensity, still exert a sudorific action far in excess of plain water. The cave baths, especially, have proved to be powerful eliminating and absorbent agents in ridding the body of large quantities of water and metabolic waste products, and, in renal disease, relieving the inadequate kidneys

and reducing edema. Indeed, the support given the kidneys is in some cases remarkable and substantiated by observations of, for instance, inebriates with alcoholic nephritis in whom the outbreak of delirium has been apparently averted by the timely application of the baths in conjunction with rational medical treatment. Thus, my experience leads me to believe that our mineral baths, under proper medical direction, are a valuable adjunct in the treatment of renal disease, and in gout their action is nothing short of specific, the benefit derived therefrom being not only temporary, but often lasting. During the "cure" the internal administration of Yampah water is useful; acting as a mild laxative, it also stimulates the functions of the liver and gastro-intestinal tract and improves the condition of the latter.

UREMIA AND ITS DIFFERENTIAL DIAGNOSIS.[1]

BY S. D. HOPKINS, M.D.,
OF DENVER, COLO.;
PROFESSOR OF NEUROLOGY IN GROSS MEDICAL COLLEGE; NEUROLOGIST TO ARAPAHOE COUNTY AND ST. ANTHONY'S HOSPITALS.

IN THIS paper the classification of the symptoms will not be considered, as the nervous, gastro-intestinal and the dyspneic manifestations of the disease are all brought about by the action of the poison in the blood on the central nervous system. As a matter of convenience we will study the various symptoms which occur in the acute and chronic cases of this disease and later take up the differential diagnosis in full.

One of the first manifestations of uremia is the headache, which may be associated with other nervous phenomena, such as numbness and tingling sensations, itching of the skin, dizziness, and gastro-intestinal disturbances. These symptoms are always found in the chronic cases and one or all may precede the drowsiness or usher in an acute attack. The headache is usually dull in character, occipital, extending down the neck.

At the Arapahoe County Hospital I have seen a number of cases in which the headache was unilateral and the paralytic symptoms which followed corresponded to the side on which the headache occurred; at the autopsy edema of the brain was found on the cerebral hemisphere opposite to that of the motor paralysis.

These symptoms may appear suddenly or gradually without any suspicion of disease of the kidneys. Drowsiness is an early symptom and may be slight or severe in degree, and if it is intense it soon passes into coma. The coma from uremia is not as pronounced as that found in cerebral disease. Preceding or during the coma convulsions varying in degree and not localized to any portion of the body may take place, although in the majority of cases one side is more affected than the other. Gowers states: "Rigidity of limbs or local muscular twitching during the coma is, if constant in seat, in favor of cerebral mischief; if variable in position, it is in favor of uremia."

Acute mania, delusional insanity and melancholia may develop, although the latter is not frequently seen. Dyspnea of a hissing character resembling the paroyxsmal attacks seen in leucemia is a typical symptom of the chronic form.

Bradford says, "More frequently, however, the dyspnea is only the accompaniment of other uremia manifestations, and its peculiar hissing quality in a drowsy patient, with bleeding gums, is very characteristic of the uremic state."

In the acute cases the dyspnea is paroxysmal, while in the chronic it is hissing and soon becomes Cheyne-Stokes in character. Monoplegia or hemiplegia may develop after a convulsion or come on gradually without any apparent cause. Frequently in chronic Bright's disease insomnia is a very troublesome symptom and is associated with cramps, twitching, and hiccough without any disturbance of consciousness. The pulse is full, strong and slow early, but as the uremic state becomes deeper it is increased in frequency. The pupils are usually equal although in the majority of the cases seen by the writer the pupils have been contracted, and in one case of interstitial nephritis all the symptoms corresponded to those of opium-poisoning, *i. e.*, contracted pupils, slow respiration, slow pulse, loss of reflexes, deep coma, although a slight trace of albumin and a few casts were found in the urine. One must always bear in mind the peculiar physiognomy in these cases and at times may detect the odor of urine in the breath. The temperature is either normal or subnormal, and when a rise of temperature is present it can be accounted for by some inflammatory process in the body. Suppression of urine may be one of the first symptoms and is a constant one. When vomiting accompanies the scanty urine the vomited material sometimes has the urinous odor. In some cases typical albuminuric retinitis is present and the patient may complain of impairment of vision or may be totally blind.

There is a form of uremia called from its very light symptoms "latent uremia" and due to complete obstructive suppression of urine. The symptoms are as follows: Little headache, nausea, pupils contracted, tongue dry, temperature subnormal, weakness and drowsiness and toward the end slight twitching of the muscles. The most trustworthy signs are the contracted pupils, subnormal temperature and no loss of consciousness.

In making a differential diagnosis the various diseases of the nervous system are first to be thought of. Cerebral hemorrhage may be simulated by the uremic state, but the constant hemiplegia associated with conjugate deviation of the eyes, together with deep coma and inequality of the pupils, would suggest hemorrhage.

Unilateral convulsions are always in favor of cerebral mischief. Local muscular twitching or rigidity, if constant in seat, is an indication of disease of the brain; whereas if it is variable, it is probably due to uremia.

[1] Read in the symposium on Diseases of Kidney before the Colorado State Medical Society.

The temperature in uremia is usually normal or subnormal, while in cerebral hemorrhage it is subnormal at first; later on fever is developed which is higher on the affected side. In uremia the temperature of the body is the same on both sides and is usually due to some complication, such as pneumonia or other inflammatory condition.

The face has a characteristic waxy hue in renal disease, whereas, in hemorrhage it is flushed with the throbbing carotids. If albuminuric retinitis is present, associated with albumin and casts in the urine, without any localizing symptoms, cerebral hemorrhage can be excluded. The same points hold good in cerebral thrombosis and embolism, excepting that in the former we have the prodromal and the local symptoms developed without any disturbance of consciousness or only slight in degree and of short duration.

Latent uremia simulates this vascular lesion more than any other form of the disease. We are not justified in making a diagnosis of cerebral embolism unless a definite cause is discovered, such as endocarditis, a suppurative process in some portion of the body, the parturient state, or blood changes often found in chronic syphilis, with exhaustion. Simple apoplexy of the aged has the same symptoms as the vascular lesions without any pathological change to be found. In tumor of the brain the history of the case, with distinct localizing symptoms associated with marked choking of the optic disks, would be sufficient to exclude uremia, for in kidney disease the degenerative changes which take place in the retina are characteristic. Suppuration in some portion of the body, particularly middle-ear disease, irregular temperature, slight swelling of optic disks, permanent unilateral symptoms are the principal ones of abscess of the brain. Meningitis may be a complication of uremia, or the symptoms in kidney disease may closely resemble the former, but the irregular, slow pulse, rigidity of posterior neck muscles, increased temperature, involvement of cranial nerves, and irregular respiration are typical of meningitis. The pulse in meningitis is the same as that found in uremia, being slow at first and later becoming rapid.

In simple syncope we have no convulsion, rigidity of the muscles, paralysis or any degenerative changes in the retina.

In chloral-poisoning the patient is in a deep sleep without any twitching of the muscles, whereas in uremia as the case progresses the twitching is especially seen in the forearms. The history of the case and absence of any evidence of renal disease would exclude chloral-poisoning. The smell of alcohol is frequently detected in the breath in unconscious cases, but should only be given weight when there is an absence of symptoms of constitutional disease and affections of the nervous system.

The coma in alcoholism is always noisy in character and is never preceded by convulsions. The appearance of the pupils is of little value, for they may be normal, contracted or dilated. In alcoholism paralysis never occurs unless there is a complication, such as peripheral neuritis or a cerebral vascular lesion.

The typical symptoms of the second stage of opium-poisoning are contracted pupils, slow respiration, four, eight or ten per minute, slow pulse, dilated capillaries of the face, and in the absence of albumin or casts in the urine would guide one in arriving at a definite conclusion.

Lead-poisoning may be mistaken for uremia as the attack may be ushered in in the same manner, but the presence of lead in the urine and the blue line of the gums would remove all doubt.

In diabetes mellitus the nervous symptoms and coma may be profound, but the large quantity of sugar in the urine would be sufficient to make a diagnosis. The uremic convulsions may be epileptic in character, but the history of previous attacks, with the tonic and clonic stage, flushed face, biting the tongue during convulsion, the short duration of the attack, and absence of any symptoms of renal disease would prevent a mistake. It is a difficult task to make a differential diagnosis between epileptic coma and uremia when a previous history of the case cannot be obtained. In the latter, however, the increased arterial tension, albumin and casts in the urine, degenerative changes in the retina and hissing respiration would serve to distinguish it from the former.

A malingerer may feign the symptoms of uremia; the two most frequently feigned by these persons are convulsions and coma. Convulsions which are variable in degree and not localized in any particular portion of the body are characteristic of renal disease, while the feigned spasm is general with an absence of any other signs of kidney disease. In the coma of malingering the pulse, respiration, and pupils will be normal, and all other signs of kidney disease will be absent. A person who is feigning coma can be detected by making severe pressure over the supra-orbital nerves or pricking the patient with a pin, causing a voluntary movement of the limb or an utterance of abusive language. This is not true of coma due to the kidney disease, if it is intense.

Hysterical coma is usually seen in females and is ushered in by delirium or may come on suddenly. The temperature may be raised, if severe muscular exertion has been made; otherwise it is normal, as is the pulse. There is retention of urine, but all other indications of renal disease are absent.

In cerebral anemia produced by sudden loss of blood, headache is rare; although in anemia caused by blood states, headache is general and neuralgic in character, associated with drowsiness, vertigo and mental dulness. These symptoms are present in uremia, but are not relieved when the recumbent posture is assumed, as they are in anemia of the brain. The history of the case, absence of degenerative ocular changes, and urinary symptoms will aid in making a differential diagnosis.

The symptoms of cerebral congestion are just

the opposite to those of uremia and are as follows: Face flushed, throbbing carotids, conjunctivæ injected, temperature elevated, full, strong, rapid pulse, no twitching of the muscle and a history of exposure.

Convulsions or coma which are seen in paretic dementia, chronic alcoholism and syphilis, can be detected by symptoms which point to organic disease of the brain.

THE CARDIO-VASCULAR CHANGES OF RENAL DISEASE.[1]

BY J. N. HALL, M.D.,
OF DENVER, COLORADO;
PROFESSOR OF MEDICINE IN GROSS MEDICAL COLLEGE; VISITING PHYSICIAN TO THE ARAPAHOE COUNTY AND ST. ANTHONY'S HOSPITALS.

MANY of the most striking features of nephritis, especially of the chronic forms, proceed from the changes brought about in the cardio-vascular system by the disease. These features are chiefly dependent upon the arteriosclerosis, the high arterial tension, and the hypertrophy of the left ventricle. The weakened vascular wall, unable to withstand the high tension, especially under some sudden overaction of the hypertrophied left ventricle, gives away and cerebral hemorrhage results; or from obliterative endarteritis the nutrition of the brain, the heart muscle, the walls of the large arteries where the vasa vasorum are affected, or other important structures, suffer and a fatal result often occurs. The troubles are practically confined to the systemic side of the circulation, and are most pronounced in chronic interstitial nephritis. Although the exact relations between the high tension, the arteriosclerosis and the cardiac hypertrophy are not yet settled, their association in well-marked cases is constant.

In gout and in nephritis the smaller arteries are usually involved in the sclerotic process, syphilis having a certain predilection for the basal vessels of the brain, and muscular overstrain affecting chiefly the aorta and large arteries. The reason for the especial involvement of the renal arteries is supposed to be that they are particularly exposed to the irritation of the waste products they are called upon to eliminate.

The nodular form of arteriosclerosis, according to Thoma, may lead to such localized weakening of the vessel-wall as to favor the production of aneurism; the senile form may be very general and accompanied by senile atrophy of liver and kidneys, yet the heart is often not enlarged; while the diffuse arteriosclerosis, found in muscular middle-aged men, particularly negroes, is accompanied by marked hypertrophy of the left ventricle. Increased consistence is always to be found in the kidneys. Although the sclerotic changes in the arteries may not be particularly notable to the naked eye, under the microscope the evidence of this change is always decisive.

[1] A contribution to a symposium upon Diseases of the Kidney, before the Colorado State Medical Society, June 19, 1901.

Mahomed believed that in the red, granular, contracted kidney the disease was generally primary in the vessels. The kidneys may be small, we are told by Osler, perhaps weighing no more than one ounce and a half, with great thickening of the small arteries. The view most favorably received at present is that the chief trouble "is in the secreting tissue of the tubules and the glomeruli, and that the connective tissue overgrowth is secondary to this." Mott states that the capillaries of the glomeruli show the hyaline change especially well, and that they are thereby frequently obliterated.

Fagge, quoting Cohnheim, believes that the small vessels of the kidney regulate the amount of blood in that organ, not in accordance with the amount needed for its nutrition, as in other tissues, but in accordance rather with the amount of waste matter contained to be eliminated. In case of destruction of portions of the kidney tissue the remainder must shoulder the whole burden, an increased pressure being obviously indispensable. To increase the pressure in this part of the vascular apparatus it is, of course, essential that it shall be maintained at a high point throughout the body.

Thoma, as quoted by Allbutt, found by injection experiments upon cadavers that fluid could be injected more readily and in much greater amount into the vessels of the subject free from atheroma than in one with marked arteriosclerosis. He concluded, further, that the capillary walls in the latter case were much less permeable to fluid. Mott suggests that the capillary area of the general circulation is greatly diminished on account of the fibrotic changes.

In the brain, in addition to the usual atheroma, an added source of danger exists in the well-known miliary aneurisms. It is thought that one reason for their great frequency here lies in the atrophy of the brain substance around the arteriole, and consequent loss of support to the vascular wall. Another reason is that the vessels are terminal in their nature, and derived directly from large trunks. F. W. Mott states that of 1,600 autopsies at Charing Cross Hospital there were 60 cases of cerebral hemorrhage. Thirty of these occurred in the subjects of interstitial nephritis with hypertrophy of the heart. Fagge lays stress upon the same point. Lancereaux in 61 cases of arteriosclerosis found interstitial nephritis in 55. We may readily conclude that the greatest predisposing cause to cerebral hemorrhage is interstitial nephritis with its accompanying arterial degeneration.

All these points considered, it is not strange that we have cerebral hemorrhage so frequently as the last event in chronic Bright's disease. We have the damaged cerebral arteries, with, frequently, the miliary aneurisms spoken of, and the high arterial tension because of the hypertrophied left ventricle. It is to be expected that, sooner or later, a little temporary increase in this pressure, owing to sudden exertion or otherwise, will cause the fatal rupture. Mott states that apo-

plexy is rare in the absence of cardiac hypertrophy, even though atheroma be well advanced.

The hypertrophy of the heart may not be confined to the left ventricle in extreme cases, but may involve all the cavities, and give an organ weighing three or more times as much as normal. This is probably in part due to the contraction of the muscular coat of the arterioles under the irritation of waste ingredients circulating in the blood and in part to the obliteration of much of the capillary outlet through the kidney, as mentioned by Traube. Many of the fibroid and fatty degenerations of the cardiac muscle are directly due to atheroma of the coronary arteries sequential to interstitial nephritis. Deterioration of the muscular power in these cases means dilatation, relative insufficiency of the mitral valve, and dropsy of the lungs and, finally, of the whole system, if life be prolonged. The edema is in part due to the cardiac failure, in part to the capillary changes and the hydremic condition of the blood. In these renal cases cardiac failure is of relatively greater importance than in others, since it is solely by virtue of the high tension that the kidneys continue to act. In the absence of a serious nephritis the outlook, while less gloomy, is nevertheless grave.

The direct source of the diminshed blood supply through the coronaries is generally a gradually-developing obliterative endarteritis, possibly more marked in certain areas than in others. With such a condition there is always the danger of thrombosis or embolism, with sudden cutting off of the remaining blood supply and almost immediate death.

It is in just such cases as these that angina pectoris is so common. The frequent association of atheroma, angina and aortic regurgitation is to be noted. This form of valvular disease, in these cases, commonly originates in an extension of the atheromatous process of the aorta to the segments of the valve, while the regurgitation at the mitral orifice, as already mentioned, is by a totally different mechanism. The aortic leakage may supervene years after the renal, arterial, and cardiac signs of interstitial nephritis are well marked. Thus I have examined this week a gentleman over seventy years of age, who, two years ago, had an increased amount of urine, with albumin and hyaline and granular casts, hypertrophy of the heart to such an extent that the apex beat was to the left of the nipple, and calcareous arteries. With the exception of marked accentuation of the aortic second sound his heart sounds were then normal. He has now developed a long, soft, blowing diastolic murmur, traceable from the second right interspace to the apex, undoubtedly due to regurgitation from a damaged aortic valve, and presumably by the extension of the atheromatous process mentioned.

Of gangrene of the extremities, especially the lower ones, from a similar process, we need not stop to speak. It does not differ essentially from that found in the absence of nephritis.

Owing to the narrow time-limit necessarily imposed in this symposium I shall touch but momentarily on treatment. Of prognosis it is necessary to say that it must eventually, perhaps only after years, in the cases with albuminuria, palpable arteries, hypertrophy of the heart, high tension and consequent aortic second accentuation, be that of the senility of which it is practically an anticipation. It is probable that iodide of potassium does more good than any other remedy in mitigating the symptoms and delaying the progress of arteriosclerosis. A diet such as one would recommend in gout, with free use of mildly alkaline mineral waters, is in order. The nitrites are most likely to relieve the high tension and associates dyspnea, anginal pain and headache. The eventual cardiac failure and the accidental complications of the disease must be treated as under other conditions.

RENAL FUNCTIONS AND LIFE INSURANCE.*

BY CLINTON G. HICKEY, M.D.,
OF DENVER, COLORADO;
CLINICAL ASSISTANT IN MEDICINE, DENVER COLLEGE OF MEDICINE, MEDICAL DEPARTMENT OF THE UNIVERSITY OF DENVER.

LIFE insurance interests have developed in the past thirty years to such magnitude that a physician can no longer afford to look lightly upon examinations for insurance. "In the United States on January 1, 1899, the level premium companies reported business representing a total insurance in force of $6,825,037,770; and the assessment companies and fraternal orders, an amount stated as $7,779,428,000. In short, nearly 15,000,000 policies were then in force, and $14,624,465,770 is the stupendous total. Nearly every dollar of this great liability represents the opinion of members of the medical profession."[1]

It has been estimated that about one-sixth of the applications for life insurance at standard rates are refused, all causes being taken into consideration, and that at least one-fourth of these rejections are based upon the presence of albumin in the urine.[2] One-twenty-fourth of the total number of applicants! Plainly, they are not all sufferers from irreparable damage of the kidneys.

On the other hand, a proportion of death losses of 10 to 12 per cent. from kidney diseases, as estimated by some life insurance statisticians, shows that in many cases not enough care is exercised in urinary examinations. One conservative old-line company, in its report for 1900 shows 8 per cent. of its death losses from kidney diseases, as against about 10 per cent from tuberculosis. This, too, is not a company which does any sub-standard business.

In securing a sample of urine for examination it is well to be sure that it was passed by the applicant. Cases of substitution come to light not infrequently. Greene cites one which recently came to his notice in which an obliging friend loaned a sample of his normal urine

* Read before Colorado State Medical Society, June 19, 1901.

to an applicant whose own urine by later examination was found to be highly albuminous.

At present most companies require chemical examination of urine in all cases; in a list of twenty-four companies I find but one which requires more than a single chemical examination, except there be two examiners, and that only when the amount asked for is $30,000 or more. Microscopic examination is in most cases not expected, except when specially requested by the company, and this only in suspicious cases. Tests for reaction, specific gravity, sugar and albumin are the only ones commonly required. A persistent alkalinity would suggest the bladder. Some neurasthenics with copious urinary deposit of oxalate of lime crystals have a urine with persistent alkaline reaction.

A high specific gravity may mean but a temporarily concentrated urine, one which will deposit urates on cooling, it may be, and which heat will render clear. The heavy urine of a chronic parenchymatous nephritis would contain an amount of albumin easily determined, together with casts, epithelial, granular and hyaline. There would probably be found, too, at least a suggestion of edema at the ankles, even in slight cases. If high specific gravity be due to the presence of sugar it will be easily shown by either Haines' or Fehling's test. It will not be forgotten, however, that a urine with specific gravity as low as 1015 may contain sugar if, in addition to diabetes, there be interstitial kidney changes.

A urine of very low specific gravity, say 1003 to 1010 may signify the polyuria of diabetes insipidus, especially if it be a young male; if it be a young female it will more probably be that of hysteria. If the applicant is nearing middle life, a urine of the specific gravity mentioned, 1003 to 1010, demands serious consideration, which leads at once to the most important part of this entire discussion, *viz.*, the presence of albumin, either with or without casts; the significance of both and the prognosis of these cases from the life insurance standpoint.

The whole question of albuminuria still continues, as it has been, a moot one. That it is not regarded now, as formerly, as diagnostic of Bright's disease is, however, unquestioned.

"The number and variety of the pathological relations under which albumen may appear in the urine compel us to regard it as dependent not only upon inflammation, grave congestions and other coarse organic changes, but upon slight variations in the mechanical conditions of the circulation in the kidney. Excluding accidental admixtures of blood or pus from the bladder or urethra, albuminuria is met with not only in acute and chronic Bright's disease, but in diseases of the heart, lungs, and liver, in peritonitis, pregnancy, abdominal tumors, in most febrile and inflammatory diseases. In many cases of poisoning, in cancer, tubercle, and syphilis; in lardaceous disease, in anemia, debility, dyspepsia, purpura, scurvy, after paroxysmal hemoglobinuria, in gout, in delirium tremens, in various diseases of the brain and spinal cord, in epilepsy, in certain skin diseases, as well as in apparently healthy persons after bathing, exercise, etc."[3]

A so-called physiological albuminuria has been observed and studied by Leube, Grainger Stewart, Stirling, Senator, and others, as occurring in the apparently healthy in from 4.2 to 44 per cent. of those examined. In these exercise and posture seemed to modify the amount of albumin, it being increased by active exercise and also by the erect posture.

To this class belong also the two forms of latent albuminuria described by Moxon in 1876. The first he called the albuminuria of adolescence. It occurs in youth or young men and is nearly always present in some specimen of the urine collected for forty-eight hours. The other form he called remittent albuminuria, renamed cyclical albuminuria by Pavy. In this, urine passed after breakfast usually contains albumin; there is then a remission and the early morning urine contains none.

Saundby,[4] speaking of this class of cases, says: "I do not care to contend that there is not some departure in these cases from the normal mechanism of the renal circulation; but it is certain that neither this lesion nor the loss of albumen gives rise to any derangement of health which impairs the working capacity of the individual or tends to shorten his life; in other words, there are cases of albuminuria which not only do not require medical treatment, but may be safely accepted by life assurance companies."

Others look upon these albuminurias as being accompanied in all cases by a slight lesion of the epithelial lining of the uriniferous tubules and, therefore, pathological in character; easily recovered from, it is true, but resulting at length, if continually repeated, in permanent pathological change.

Clement Dukes,[5] who has devoted much attention to the albuminuria of adolescence, says: "The cases of early albuminuria, so common in the young, constitute the early stage of what may eventually become developed into that chronic disorganization of the kidneys termed Bright's disease."

So excellent a clinician as Osler, in his "Practice of Medicine," says: "The physician is daily consulted as to the relation of albuminuria and life assurance. As his function is to protect the interests of the company, he should reject all cases in which albumen occurs in the urine. It is even doubtful if an exception should be made in young persons with transient albuminuria."

In the matter of casts and their estimated importance there exists at the present time the same dissonance of opinion. Any one who has made any considerable use of the centrifuge

must have been impressed by the frequency with which a stray hyaline cast or two has been encountered in urine presenting no other evidence of kidney disease. Haines and Skinner[6] claim that by their careful methods of search casts may be found in the urine of persons in perfect health.

Kobler,[7] has studied this question carefully and concludes that the true significance of hyaline casts is not known; that even granular and epithelial casts are often found when no morbid condition of the kidney exists, but when there is gastro-intestinal disease, especially when this is accompanied by violent diarrhea, in some cases also when a condition of constipation is present.

Others, however, are inclined to regard the presence of even the hyaline casts, at least in anything more than the smallest numbers, as of serious import. In this connection I quote Purdy[8] as saying: "Numerous observers have found hyaline casts in non-albuminous urine, but the author agrees distinctly with Bartels in that he has never met with them save in albuminous urine or urine that has recently been albuminous."

By way, then, of summary, in view of the divergence of opinion on these points among competent men, I believe a medical examiner is justified in recommending for insurance an applicant *below middle life,* whose urine may have shown albumin or casts, or both, only after continued observation for a length of time, and even then only as a substandard risk. A safe exception to this rule might be made in cases in which, with other evidences of perfect health, the urine with use of the centrifuge showed but a few stray hyaline casts. *After middle life* the rule should be practically absolute *against* recommendation in the class of cases under consideration.

In many cases near or past middle life great reliance must be placed upon the condition of the heart and the blood-vessels. An apex-beat beyond the nipple line, an accentuated aortic second sound, a moderate atheroma, with a pulse of increased tension, would together be suspiciously suggestive of a contracted kidney even in the absence of any definite urinary evidences of the disease.

In this condition, with urine of low specific gravity, albumin, never present in more than minute quantity, is often absent for days together. This necessitates delicate tests and repeated examinations. If Heller's test is used the test-tube should be set aside for fifteen minutes as a trace may not show for that length of time.[9]

That there is agreement of authorities in regard to the *intermittent presence only* of albumin in many cases of chronic interstitial nephritis makes obvious the inadequacy of the single examination of urine required by most companies in ordinary cases.

The proportion of from 8 to 12 per cent. of death losses from kidney diseases, as referred to before, leads me to suggest that, in my opinion, in applicants past forty years of age life insurance companies would do wisely to require several examinations of urine for albumin, even though there be nothing suspicious in that first presented; and that a large saving would be effected, too, in death losses, if in addition the companies were willing to pay an extra fee for the use of the centrifuge and the microscope in the examination of the urine in all cases in which the applicant has passed the forty-year mark.

MEDICAL PROGRESS.

Clinical Value of Some Newer Hypnotics.—A common reason for incorrect opinion in regard to the value of hypnotics is the fact that in many cases the mental suggestion acts as powerfully as the drug itself. Another error arises from the fact that a patient who has been sleepless for several nights will frequently sleep on the testing night without any drug. A. E. BROWNRIGG (*Boston Med. and Surg Jour.*, July 18, 1901), in testing the relative merits of dormiol, chloretone and hedonal, selected cases which offered no probability of natural sleep on account of continuous nervous unrest. He concludes that dormiol is the most easily administered. Both dormiol and hedonal proved perfectly safe in ordinary dosage, even when given repeatedly to feeble patients. Dormiol excels in rapidity of action. Hedonal and dormiol are more purely hypnotic in their action than chloretone, and both give refreshing rest. The duration of the sleep with dormiol is somewhat longer than with chloretone and much longer than the sleep produced by hedonal. After the sleep produced by chloretone there is a tendency to drowsiness for some hours. The very defects of chloretone, however, make it valuable in certain selected cases. Dormiol, while not the most powerful sedative we possess, answers well the requirements for a generally serviceable hypnotic. Hedonal is especially applicable to slight forms of insomnia unassociated with bodily pain or severe mental excitement.

A Modified Plaster Splint.—J. R. BENSON (*Lancet,* June 29, 1901) has found the following a convenient and serviceable hinge plaster splint. The coverings are of flannel, outer and inner. The width of each is the length of the splint, for example, from the knee to the ankle. The length of the inner covering

permits it to pass twice around the limb, so that the redundancy may be folded back upon itself. The length of the outer covering encircles the limb half way. There the excess of the inner compensates for the deficiency of the outer. At a point corresponding with half the length of each a seam is run fastening the two together in a hinge, which is parallel with the width. This seam therefore embraces *two* thicknesses of the flannel. The pieces are now folded upon the hinge and a second seam is run a quarter-inch from the first through the *four* layers of flannel as they thus lie each to each. This second seam now becomes the true axis of the hinge, while the former creates a convenient strengthening ridge. Between the outer and inner flannel layers on either side of the hinge, the stiffening of plaster of Paris is to be inserted. The hinge-ridge passes best down the front of the limb or the side parallel with the long axis. The larger or inner piece is now wrapped about the limb and tacked in a straight line just opposite the hinge line. Between these points the plaster is applied as a bilateral molded splint and the outer flap of flannel is laid over it reinforced by the return folds of the long inner flannel. The whole is then covered till dry with an ordinary roller bandage. When the splint is hard the bandage is removed, the tacking is cut and a beautiful hinged splint is formed.

Presence of Specific Antibodies in the Blood of Animals Treated With Different Sera; Also Their Use in Legal Medicine.—The recent discovery of specific precipitates, produced experimentally in the body, which act upon various bacterial products, milks, peptone, egg-albumin and human blood, has led G. H. NUTTALL and F. M. DINKELSPIEL (*Jour. of Hygiene*, July, 1901) to investigate this subject. In their experiments only rabbits were used and the blood, pleuritic exudate, etc., were injected intraperitoneally in quantities of 5 to 10 c.c., beginning with the smaller dose and never exceeding the larger. Effective antisera were obtained after the fifth or sixth injection. They treated thus some sixteen rabbits with dog, sheep, ox, horse and cat sera, also with defibrinated blood and pleuritic exudate. Their conclusions confirm and extend the observations of others with regard to the formation of specific precipitates in the blood of animals so treated. These precipitates are specific although they may produce a slight reaction with the sera of allied animals. The substances in the serum which bring about the formation of these bodies are remarkably stable. This new test can be successfully applied to a blood which has been mixed with that of several other animals and it is the most delicate means hitherto discovered of differentiating bloods. It is to be expected that it will be put to forensic use.

Bacteriology of Vaccinia and Smallpox.—Basing his work upon the postulates that, in order to establish the pathogenesis of any given micro-organism to any specific disease, the organism must be constantly present, that it must be present in sufficient amount and in the proper location to account for the symptoms, and that it must be possible to inoculate it in pure culture into animals and produce the characteristic symptoms, M. FUNK (*Ctlblt. f. Bak.*, July 5, 1901) has investigated the bacteriology of vaccinia and variola. Upon discovering that he had to do with a protozoa of which there could be no culture in a bacteriological sense, he adopted the use of emulsions of these organisms and proved their pathogenesis to these diseases by successful animal inoculation and the production of an artificial immunity. Pus taken from a vaccine pustule remains sterile on all culture media and microscopical examination shows no bacteria. Vaccine lymph ready for use, taken from a great variety of sources, shows a great number of bacteria, the majority of which are saprophites, only a few being pathogenic and none of these being common to all varieties of lymph. This lymph when preserved for three or four months becomes sterile, probably due to the presence of glycerin, yet this sterile lymph is always active and produces typical vaccine pustules. From these facts he concludes that vaccinia is not a bacterial disease. All vaccine lymphs also contain protozoic cells some of which are filled with spores and are then known as "sporidium vaccinale." These may be easily confounded with epithelial cells if they are not observed by means of the "hanging-drop" technic. There are also free spores present in the fluid. By emulsifying these spore-filled cells in sterile bouillon and injecting this into animals he was able to produce typical vaccine pustules and also to produce an immunity to the inoculation with ordinary vaccine lymph. He therefore concludes that these bodies are the cause of vaccinia. Pus from smallpox pustules shows the abundant presence of these bodies. By means of the "hanging-drop" method and a suitable temperature, he was able to see these protozoic cells sprout and the spores develop into new cells. These bodies, taken from smallpox pustules, inoculated into calves produce true cowpox and confer immunity thereto. Hence he believes that vaccinia and smallpox are identical affections.

Congenital Lymphadenoma.—E. BONNAIRE and DECLOUX (*La Presse Méd.*, July 13, 1901) reported the case of a child who two days after its birth was brought to the hospital because of its weakness. The large abdomen contrasted strongly with the emaciated trunk and head. The weight of the infant was only 1,700 grams. The skin was very white, the features pinched and the lower extremities edematous. Physical examination revealed ascites and a regularly-enlarged liver extending to the margin of the pelvis. A voluminous mass was felt in the left hypochondrium, resembling

an enlarged syphilitic spleen, and the clinical diagnosis of congenital syphilis was made. The ascites was attributed to the supposedly sclerotic liver and the edema of the extremities to the pressure of the ascitic fluid. Cyanosis developed three weeks after birth and death followed two days later. The autopsy revealed whitish nodules, varying from 1 to 5 millimeters in diameter, in the parietal pleura, the parietal pericardium, peritoneum, and mesentery. Submucous nodules were found in the stomach and intestine, and the enlarged liver was strewn with whitish nodules of varying size. The spleen was macroscopically normal. The mass which had been palpated on the left side proved to be the suprarenal capsule, which entirely covered the subjacent kidney, the latter being normal in size and structure. Microscopically the liver, pancreas, suprarenal capsule, spleen, lungs, pleuræ and pericardium were found to be invaded by adenoid tissue.

Practical Blood Examination.—The scope of practical blood-examination at present is stated by H. F. Hewes *(Boston Med. and Surg. Jour.,* Aug. 1, 1901) as follows: (1) The determination of the existence or non-existence of anemia and, if present, of its severity and type. (2) The determination of leucocytosis, its extent and type, including the diagnosis of myelogenous and lymphatic leucemia. (3) The determination of the presence or absence of blood-parasites, including diagnosis of malaria, filaria sanguinis hominis, and relapsing fever. (4) The determination of the existence of definite serum reactions as the Widal test for typhoid. (5) The determination of the presence in the blood of bacterial organisms; that is, of septicemia. Nine-tenths of all clinical blood-work may be done by the employment of two very simple methods of examination, namely, the estimation of the hemoglobin and the examination of a stained specimen of blood. The examination of fresh specimens of blood and the use of counting methods furnish added knowledge, which, however, is frequently not necessary for diagnosis. More recently developed methods of equal practicability as yet lack the testimony of extended experience in regard to their usefulness. The most important and promising of these methods is the test for iodophilia, said to be of value in conditions of suppuration (except in tuberculosis) and in croupous pneumonia.

A Ramifying Diphtheria Bacillus.—A. Cache *(Ctlblt. f. Bak. u. Infect.,* July 8, 1901) makes further study of a ramifying bacillus found by Ouchinsky in 1900 in a tube of his mineral media in which he had sown some months previous diphtheria bacilli. He made transplants from the original culture into several new tubes of this mineral media and incubated these for three months. At the end of this time lamellæ were present in the bottom of these tubes. These on microscopical examination were found to be composed of ramifying threads. From these transplants were made into bouillon, agar, and gelatin. On gelatin and agar the growth produced a membranous formation firmly attached to the surface of the media. In bouillon no cloudiness was produced, but the formation of small white flocculi was noted. By repeated transplants into bouillon, agar and gelatin, he was able to obtain a micro-organism morphologically identical with the diphtheria bacillus, pathogenic for guinea-pigs in from thirty-six to forty hours, and producing pathological lesions characteristic of diphtheria. He thinks, therefore, that these micro-organisms were genuine diphtheria bacilli. He believes that the microscopical and cultural methods employed exclude the supposition that contamination with some filiform organism was present or that he was dealing with a case of symbiosis.

Treatment of Tuberculous Lymphadenitis.—R. Hammerschlag *(Prager med. Woch.,* July 18, 1901) states that analysis of statistics shows a higher percentage of cures by the well-known iodoform-glycerin injections than by extirpation of enlarged glands. The former method of treatment is favored also for the following reasons: It is simple, safe in the hands of the general practitioner, leaves no scar, is relatively painless, and requires no cessation of occupation on the part of the patient. No matter how the superficial and accessible cervical glands are treated, the far more dangerous bronchial and mesenteric nodes remain.

A Case of Cervical and Bulbar Tabes with Necropsy.—The autopsy in this case was performed by W. G. Spiller *(Amer. Jour. Med. Sc.,* Aug., 1901) who reports the following important findings: Degeneration of the posterior roots of the cord especially in the middle and upper thoracic region and on the left side in the lower cervical region. No distinct degeneration of the columns of Goll; very slight degeneration of the columns of Burdach. Atrophy of inferior part of the left twelfth nucleus. Degeneration of the left descending root of ninth and tenth nerves. Degeneration of the spinal root of each fifth nerve. Atrophy and changes in the nuclei of the oculomotor nerve. In the history of the case reported by S. Solis Cohen the following data are noted: Acquisition of syphilis some years before nervous symptoms developed; attacks of nocturnal incontinuence of urine beginning in 1872: ptosis of right eye in 1879; varying contraction and dilatation of the pupils; weakness of facial muscles; difficulty of mastication and deglutition; atrophy of the tongue; disturbance of sensation for temperature and pain; griping abdominal pains; neuralgic pains in lower limbs; "suspicious grayness" of the optic disc; inequality of pupils; loss of light reflex; loss of power of accommodation; failure of vision —all observed in 1888—loss of sexual power. Later there developed atrophy of the upper limbs; pain in ulnar distribution of right hand.

There was no incoordination in the upper limb movements. In 1889 the knee-jerk was still well preserved, which accords with the necropsy finding of an almost complete integrity of the posterior roots of the lumbar region.

Pathogenesis of Tumors.—CHARLES POWELL WHITE (*Jour. of Path. and Bac.*, June, 1901) reviews the theories which have been advanced to explain the origin of tumors, the relation of tumors to other pathological processes, and the growth of special tumors. He concludes that as a rule they have their origin in normal tissue-cells. The extrinsic causes of tumor formation, as far as they are known, do not differ essentially from the extrinsic causes of inflammation, etc. In the case of tumors we cannot often determine these causes; the parts, however, being in a very unstable equilibrium, a very slight cause would be able to disturb the relative position. The essential differences between progressive and reparative processes lie in the condition of the body with respect to equilibrium. In the first case this is unstable and in the second stable. It is not possible at the present day to say in what this difference actually consists. Most tumors grow by centrifugal growth. In the case of carcinoma, however, it is possible that centripetal growth may play a small part in the formation of tumor. He thinks that the treatment should not only be local, but should also be directed to the general condition of the patient.

Changes in Polymorphonuclear Neutrophilic Leucocytes in Infectious Diseases.—The existence of structural alterations in polymorphonuclear leucocytes is said by H. HIRSCHFELD (*Berlin klin. Woch.*, July 22, 1901) to be characteristic of certain infectious diseases. The alterations in question are not apparent when fresh specimens are stained with Ehrlich's triacid stain, but are seen when methylene blue or methylene green is used. In ordinary blood the granules of polymorphonuclear leucocytes are refractory to methylene blue, while in lobar pneumonia, measles with bronchopneumonia, scarlatina, and acute phthisis with high fever, the granules referred to show an affinity for this stain. The granules may be distributed through the protoplasm, as are normal neutrophilic granules, or may be concentrated in certain areas to the exclusion of others. The alteration sometimes affects all the polymorphonuclear cells, but may involve only a portion of the whole number. The reaction was obtained by the use of dry cover-glass preparations, fixed either with heat or alcohol, and stained with a 1-250 solution of methylene blue.

Anesthetics in Heart Disease.—The results of a study of 142 cases suffering from various forms of heart disease and operated on under anesthesia for various minor and grave troubles are presented by J. M. T. FINNEY (*Amer. Jour. Med Sc.*, Aug., 1901). From a comparison of the behavior of these cases with others operated upon for similar affections under the same conditions, the author concludes that in the myocardial affections only do anesthetics exert any markedly bad effects. In valvular disease their influence is slight, but appreciable; in functional disturbances, insignificant. To seven cases suffering from myocarditis ether was given; to one, chloroform and ether Five took ether badly and three took it well. In the case to which chloroform was administered it had to be discontinued and ether substituted on account of rapid, irregular and weak pulse, cyanosis and disturbed respiration.

Cardiac Hypertrophy.—JOHN GUTCH (*Jour. of Path. and Bac.*, June, 1901) has pursued investigations to ascertain whether cardiac hypertrophy is brought about by a numerical increase of the muscle fibers, an increase in the size of the individual fibers or by a combination of both of these factors. He took specimens of the heart muscle from four locations, namely, left ventricular wall at the junction of the upper with the middle third and near the ventricular septum; muscularis papillaris of the mitral valve; right ventricle, front wall of the junction of the upper with the middle third; muscularis papillaris of the tricuspid valve. He employed a micrometer eye-piece one division in the scale of which was equal to .0037 millimeters. One hundred muscular fibers were measured in each specimen. As the result of his work he believes that the increase in the size of the heart is largely due to a hypertrophy of the individual muscular fibers. The increase in the breadth of the fibers is not sufficient to account for the whole increase in the weight of the heart. Some hypertrophied hearts, especially those of interstitial nephritis, are more difficult to tease out than is the normal muscle. This probably depends upon an increase of interstitial tissue which can be seen in teased-out specimens. It is at least probable that along with the increase in breadth there is also an increase in length. These factors are sufficient to account for the whole increase in weight without supposing that any numerical hyperplasia of fibers takes place, while on the other hand no direct evidence of such hyperplasia, such as karyomitosis, has ever been brought forward.

Tracheal Tug in Conditions Other Than Aortic Aneurism.—HENRY SEWALL (*Amer. Jour. Med. Sc.*, Aug., 1901) points out that a tracheal tug quite palpable in character is in many cases associated with and dependent upon adhesions of the left pleura. Diminished extensibility of the lung tends to produce the same phenomenon, and the tug is most pronounced when these conditions are combined. In normal individuals a laryngeal jerk may likewise follow the heart-beat and the proportion of normal males manifesting the sign is double that of normal females. This is explained by the predominance of the diaphrag-

matic type of respiration in the male. The descent of the heart with the inspiratory movement of the diaphragm may so press the aortic arch upon the left bronchus as to impart to the trachea the aortic pulse, recognized at the larynx as a palpable tug.

Treatment of Urinary Infiltration, Urinary Abscess and Fistulæ.—Infiltration results usually from stricture and hence the site of escape is commonly found to be just posterior to the bulbous urethra, where stricture is apt to occur, says H. HARTMANN (*La Presse Méd.*, July 13, 1901). Two principles govern treatment; first, give free means of exit to the urine which has already found its way into the tissues; second, prevent the further escape of urine. In making free incisions to facilitate the removal of infiltrated urine, this writer prefers the bistoury to the thermocautery. Parallel incisions are recommended at distances of three to four centimeters. A wet dressing is then applied, or, to control hemorrhage the better, a dressing of iodoform gauze. By means of a perineal incision a drainage tube is introduced to carry off whatever urine may continue to find its way through the urethral lesion. The removal of the stricture is essential, but urethrotomy, if necessary, should be postponed until the tissues are restored to a healthy condition. In the treatment of urinary abscess it may be regarded as a tumor and totally extirpated, or it may be incised and drained like a common abscess.

Serumtherapy in Typhoid Infection.—E. W. AINSLEY-WALKER (*Jour. of Path. and Bac.*, June, 1901) has undertaken experimental research in order to determine, as nearly as possible, how far the value of sera was effected by the variety of the bacillus typhosus employed and what modification if any resulted from the employment of several varieties either together or in succession; also the relation of the colon bacillus to the immunity produced. After reviewing the methods used by Pfeiffer, Kolle and Bokenham, in preparing these sera, he concludes as follows: (1) There is evidence that a serum can be obtained by the immunization of horses against the bacillus typhosus. (2) The initial stages of the preparation may be greatly shortened by the method of Bokenham. (3) A high degree of immunity must be obtained and the use of living cultures in the later stages is desirable. (4) The serum must be made widely polyvalent by the use of as many and largely different races of typhoid bacilli as practicable. (5) The relative value of the serum obtained may be determined by its relative agglutinative power. (6) It is an open question whether the efficiency of the serum might not be further increased by immunization of horses against the colon bacillus also by the addition to the serum of a certain proportion of anticoli serum from a horse treated with that organism.

Cancer of the Uterine Neck.—It is maintained by J. M. BALDY (*Jour. of Amer. Med. Assoc.*, Aug. 3, 1901) that cancer of the neck of the womb, as far as results go to-day, is practically incurable. A careful analysis of reliable statistics, says this author, will show that where 20 to 60 per cent of cures are claimed, the percentage of real cures is nearer 2 to 5 per cent. Hemorrhage, with beginning loss of flesh and strength, is the diagnostic feature of the early stages. Where there is a single show of blood several years after the menopause, no matter from what exciting cause (traumatism excluded), cancer should always be suspected. Even during a woman's menstrual life, the family doctor should suspect cancer in every case of irregular bleeding not otherwise readily explainable. Even very minute quantities of blood appearing at times incompatible with the physiologic flow demand rigid attention.

Hemolysis.—The efficacy of transfusion of blood has been doubted for some time on account of the suspicion that the blood of one animal acts as a toxic agent to the blood-cells of another. Transfusion, even of blood from one person to another, has now been generally discarded, since the susceptibility to hemolysis has become so thoroughly understood. S. J. MELTZER (*Med. Rec.*, Aug. 3. 1901) has made a careful study of the action of the blood of one animal upon the blood of another and finds that when a bullock's blood, for instance, is injected into the peritoneal cavity of a rabbit it soon becomes so changed that it loses a part of its power to cause a destruction of the blood-cells of the rabbit when injected into the rabbit's jugular vein. Again, the normal serum of a guinea-pig which has very little or no effect upon the red corpuscles of a rabbit, may acquire a marked hemolytic power if the guinea-pig is treated several times by subcutaneous injections of rabbit's blood. This is called "hemolysis by immunization," and such facts as this disclose the possibility of various interesting and valuable therapeutic measures. One practical application is found in the fact that by injecting human blood into rabbits the serum of the latter is caused to take on a characteristic turbidity and a flocculent deposit is caused in the human blood even if this is in the form of an old small dry spot. Human blood may thus be distinguished from that of any other animal with absolute certainty, except from that of monkeys.

Mental Disturbances in Cardiac Disease.—Psychical disturbances in cases of cardiac trouble are extremely common, but very little attention is paid to the exact causes of the trouble. A. ZEDERBAUM (*N. Y. Med. Jour.*, July 27, 1901) says that there is no consensus of opinion among clinicians as to the causal relation between abnormal functions of a diseased heart and these mental disorders. It is easily understood, however, how the nutrition of the brain would be greatly influenced by an impaired circulation. Altogether, psychoses are more frequently observed in connection with aortic defects than in failure of the mitral valves. The symptoms of mental disturbance here partake more of the nature of mania and resemble the delirium of an alcoholic pneumonia. Extreme irritability, ex-

citement, fretfulness, restlessness and inconsistency make it sometimes very difficult to control the patient. Suspicions of insanity may even enter the minds of the observers and at times outbreaks of real mania do occur. Troublesome and exhaustive sleeplessness are especially noticeable in aortic insufficiency. Mania and melancholia seem to be the most common forms of mental alienation in cardiac cases and these are also most prevalent in cases of puerperal insanity which the author believes depend largely on the cardiac condition.

Treatment of Infantile Diarrhea.—W. H. ROBEY, JR. (*Phila. Med. Jour.*, July 27, 1901) states that, although the specific cause of infantile diarrhea is unknown, the condition is first a local one, due to the toxic products of enormously-increased numbers of bacteria, and later constitutional symptoms develop from the absorption of these products. The treatment is as follows: (*a*) Cleanse the bowel of bacteria and their toxic products by the use of one grain of calomel in one-tenth-grain doses at half-hour intervals, combined with colon irrigations. (*b*) Provide unsuitable culture media for the bacteria by withholding food for twenty-four hours and giving sterile water at frequent intervals. It is perhaps well to allow the mother to think that she is giving a food in order to carry out this important part of the treatment. For this purpose albumin-water (whites of two eggs, a pint of boiled water, a pinch of salt and a teaspoonful of brandy) may be employed, a half a teacupful being given every two hours. Vomiting may be relieved by washing the stomach, using a soft rubber catheter, and a high temperature lowered by a tepid bath. After twenty-four hours the child should be put on a weak modification of sterilized milk. (*c*) Soothe an irritated intestine when the long-continued condition makes it necessary. (*d*) Support the patient against constitutional symptoms, as in other acute diseases of childhood. (*e*) Guard against infection of others by isolation, when possible, and scrupulous cleanliness.

Ruptured Uterus in a Multipara.—J. POLLOCK SIMPSON (*Brit. Med. Jour.*, July 13, 1901) reports a case in which the direct cause of rupture seems undoubtedly to have been due to the struggles of the child. These violent paroxysms were induced by the mother's chopping off the protruding arm with a bread knife. It was a posthumous child, but the husband had been dead twelve months. The mother in her effort to conceal the birth had adopted this radical method of accouchement and the child retaliated with lethal interest.

Diplococcus Rheumaticus.—F. J. POYNTON and A. PAINE (*Lancet*, July 13, 1901) report on arthritis produced in rabbits by the intravenous injection of a diplococcus isolated from cases of rheumatic fever. It is a small germ which they have demonstrated in eighteen cases. They believe it to be identical with the diplococcus of Triboulet and Wassermann. Their conclusions, deduced from a large number of cases of arthritis in rabbits are as follows: Arthritis is frequent, but not invariable. It is a polyarthritis, affecting especially the largest joints. The severity varies and recovery is either partial or complete. The exudations are clear, blood-stained, turbid or fibrino-cellular. The germ is found in the exudations, but with difficulty in the most acute and in the chronic cases. It probably gains access to the joints by the blood capillaries in the areolar layer of the joint capsule.

Myelopathic Albumosuria.—T. R. BRADSHAW (*Brit. Med. Jour.*, July 13, 1901) reports a case of this rare disorder, making the total sixteen. It illustrates two important points, one of which is new. (1) The presence of albumose in the urine is the earliest symptom of the disease and it exists for months without evidence of failing health or local signs of alteration in the skeleton. (2) The albumose is first excreted in small amounts, but, as in many cases of ordinary albuminuria, since it causes no inconvenience, it is often undiscovered till the disease is far advanced.

Recurrence of Experimental Malaria.—P. THURBURN MANSON (*Brit. Med.* Jour., July 13, 1901) cites his own case. He was exposed to the bites of mosquitoes fed in Rome on a case of benign tertian ague and in ten days developed a typical tertian fever. Quinine treatment was continued for three months. Nine months from the time he was bitten Dr. Manson developed symptoms of malaria. These were sufficiently severe to confine him to bed; his temperature rose to 103° F. Blood films showed both young and old forms of the parasite of double tertian ague.

Diachylon as an Abortifacient.—W. WRAUGHAM of Wadsley (*Brit. Med. Jour.*, July 13, 1901) reports the alarming increase of women who are more or less seriously injured by the use of lead pills administered by midwives and abortionists. Just as the use of phosphorus, arsenic and other poisons, is swayed by fashion and interestingly governed by locality, the exhibition of this most dangerous abortifacient is more or less of a fad just now and is restricted to Leicester, Birmingham and Sheffield. The important points gathered from a study of five cases are as follows: The primary effect of the poison is on the nervous system,—not on the stomach nor gut. No less than four cases presented grave optic neuritis and ocular paralysis. The incubation period of lead, if such it might be termed, is shown to extend over several weeks and frequently there were no symptoms till after the drug had been stopped. The purely social-economic side of this question, quite apart from any ethical considerations, is of vast import. Particularly is this true when one considers that not only are the mothers almost invariably killed or permanently crippled—blindness being very frequent—but the children occasionally survive to drag out a helpless life at the expense of the State. The writer ably asks why, if the Home Secretary be notified of the industrial forms of lead-poisoning, he should be kept in ignorance of this, the most pernicious of all.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, AUGUST 10, 1901.

DIURETICS IN KIDNEY DISEASE.

A PROPER study of diuretic medication presupposes a knowledge of the physiological phenomena underlying diuresis. While many facts are known regarding the grosser mechanical factors concerned in such action, it is unfortunate that we are far from knowing the more intricate and subtle changes that take place in the renal tissues, especially since painstaking observations have been in progress for at least fifty years.

From the first anatomical studies of Malpighi and Henle, and the physiological researches of Bowman, to the present time, hypotheses as to the relative importance of this or that histological element as the active factor in the elimination of the various urinary constituents, liquid and solid, have had their brief day on the stage of popular belief and have then passed into the realm of the disproved, if not forgotten.

In the present issue of the MEDICAL NEWS we present a series of papers bearing on disease of the kidneys and in the report of the investigations of Dr. Elliott is set forth a noteworthy contribution to the eminently practical problem of the relationship of diuretic medication to renal disease, taking into account the present status of the much-vexed question of kidney physiology and diuretic action.

At the same time we would call the attention of our readers to an interesting research made by Henri Anten (*Archives Internationales de Pharmacodynamie et de Thérapie,* Vol. VIII., fasc. v., vi) on the diuretic action of caffeine and theobromine. This investigator has gone over the entire ground and, while arriving at many conclusions already well grounded, has served to establish more fully the principles that should guide one in the use of the xanthin derivative group of drugs.

He shows that, as a primary consideration, it may be taken as proven that the epithelium of the convoluted tubules of the ascending loop of Henle is the important factor in the elimination of uric acid, in major part at least, and, it may be in less degree, urea. He moreover emphasizes the fact, now fairly well established, that the xanthin bodies stimulate renal epithelium and thus aid in the elimination of nitrogenous substances. In marked contrast to this action of the xanthin bodies is the influence of salines, which by stimulating the glomeruli favor the elimination of water and of inorganic salts, notably the chlorides.

The xanthin bodies then by their specific action in stimulating renal epithelium, bring about increased elimination of urea, water, nitrogenous bodies and it may be of some salts as well, and thus render the blood poor in urea and in salines; it thereby eliminates less of these bodies as the diuretic action progresses; on the other hand, the saline diuretics incite a watery diuresis which renders the blood richer in uric acid and urea.

Several practical lessons are suggested by these results; thus, in acute parenchymatous disease of the kidneys, as Elliott has already pointed out, diuretics may be of little avail, certainly the xanthin diuretics, caffeine and theobromine, are contra-indicated; whereas in subacute and chronic conditions, associated with diminished uric acid and urea output, they may prove distinctly valuable. A further interesting dietetic factor is brought into prominence, namely, the use of nitrogenous food, especially those rich in proteids which in their normal katabolism break down to xanthin bodies,, guanin, adenin, etc. From early days it has been taught that meats should be avoided, and certainly for the acute

stages the reasons are apparent, but it is quite an open question whether or not a limited amount of meat might not prove at least harmless in the treatment of chronic Bright's disease.

DOG-DAYS AND RABIES.

WE are passing through what are called the dog-days. In many parts of the country local tradition gives this name especially to the latter part of July and the beginning of August. The exact limits of this supposedly fell season are not definitely settled, for all during these two months it is popularly credited that dogs are much more liable to go mad. The heat and lack of sufficient water are supposed to be the active agents in the increase of madness among dogs at this time, and many elaborate theories have been evolved to account for the occurrence of the disease.

It seems almost too bad to take away the occasion for this brilliant theorizing, but the facts are all against the supposition that more dogs go mad in the summer than in other seasons. For so long as we have accurate statistics on the subject, rabies has been more frequent in the latter months of winter and the beginning of spring than at other times of the year.

As a matter of fact the dog-days are so-called, not with any reference to our domestic pet animals, but because Sirius, the dog-star, is during July and August in its heliacal ascendant. The Latins had the habit of calling this star simply *canis,* the dog. The popular imagination, after the original derivation of the term dog-days—the time of the dog-star—was lost, clothed the words with a new significance. This popular error has been and is yet, the source of no little apprehension. It is practically only at this time that the general public take any interest in the possible spread of rabies, because dogs are allowed to run loose without let or hindrance. At all other times the great principle of personal liberty is supposed to be sufficient justification for every citizen maintaining his portion of the nuisance that the presence of dogs on our city streets involves.

Rabies or hydrophobia is not a common disease, but careful investigation shows that the affection is on the increase in this country. D. E. Salmon, Chief of the Bureau of Animal Industry of the United States Department of Agriculture, makes the following statement in an article in the Year-Book of the Department for 1900: "It may safely be concluded that instead of being a much rarer disease than is generally supposed, rabies is a much more common disease than we had reason to expect." Salmon only reechoes the views of all the Boards of Health throughout the country which have seriously taken up the investigation of the disease.

It used to be a favorite theory of many people, including even some medical men, that rabies did not exist at all or, at least, did not exist in this country. Its supposed symptoms were set down as neurotic manifestations in hysterical or high-strung persons on whom the stories of hydrophobia following dog-bite produced a profound effect. American physicians who harbored any such notions were rudely shocked by finding how more and more seriously the disease was taken by European medical and civil authorities. No important nation in Europe is now without special regulations for the prevention of the disease and special stations for its specific treatment.

Well-authenticated cases of rabies occur in the hospitals of our large cities every few months. There is no longer any plausible reason to doubt the existence of the disease in this country. Since the establishment about two years ago by the German Government of a Pasteur Institute for the treatment of rabies, there is no reasonable excuse for the slur so common before, namely, that Pasteur had invented a treatment of which we know nothing for a disease the cause of which we know even less. Rabies is one of the diseases that, like tetanus, brings with it suffering and eventually death for those who were only just before strong and healthy. It is especially sad in its ravages, because it takes for its victims, as a rule, not the weaklings, but those who are in the prime of life and vigor. Its eradication therefore would be one of the unmixed blessings that sanitary regulation could confer on our generation.

It is almost needless to say that the disease does not originate even in animals because of heat or from lack of water, or from poor nourishment. Rabies is a specific disease the germ of which we do not as yet know, although we have now no doubt of its existence. The affection is spread by the inoculation of the virus of the disease into healthy animals or human beings. The saliva of affected individuals contains the germ of the disease and it is by this secretion that inoculation takes place. It affects many animals besides the dog, but dogs being practically the only animals allowed at liberty they are the usual transmitters of the disease. If all dogs in New York State were to be muzzled for six months, and thereafter all dogs imported into the State required to wear an effective muzzle for the same

length of time, we would be rid of the danger of rabies forever. The disease is not rare in this State and last winter its presence became so noteworthy in the Western part of the State as to excite serious alarm. The repressive measures mentioned would not seem severe even to the overwrought imaginations of our antivivisectionist friends. Their enforcement would be a cheap price to pay for the riddance from fear on the part of many timorous individuals that would follow.

There is no good reason why so many dogs should be allowed to run at large as at present. While it is a generally accepted axiom in public polity, it would be very hard to prove that every man who wishes has an inalienable, God-given right to own a dog and to allow that dog to be as much of a nuisance as his dogship wills and his master (or mistress) permits. It is probable that dogs are also bearers of diseases other than rabies. They are, for instance, by no means as immune to tuberculosis as was formerly thought. It seems likely that they are sometimes the source of human tuberculosis in children. Their relation to the echinococcus as the source of that parasite for human beings is well known. The dog-days and the apprehension of pet animals that they occasion might well serve as an opportunity to physicians for the formation of a proper public opinion with regard to the utter inadvisability of allowing these animals the liberty of our streets, not alone during the hot weather, but at any season of the year.

WHERE TO SETTLE.

THIS unusually puzzling and all important question is occupying the minds of at least some hundreds of recent graduates in medicine. There are, naturally, many circumstances that must be taken into account in its answer.

So far as the material elements of the problem are concerned, the recent census furnishes some interesting statistical considerations. The number of inhabitants to doctors in this country is not large. There are for each physician only 1,215 people. In many States the number of inhabitants to each physician is much lower than this. Some of the States and territories are especially scant in their provision of physicians for possible patients. It might seem that in some of these inadequately-supplied States the recent graduate in medicine would find a welcome that is only too long delayed in regions medically better provided for.

Mississippi, for instance, has but one physician to every 1,548 inhabitants; New Mexico, one to every 1,406; North Dakota, one to every 1,347. There are more than 1,100 inhabitants to each physician in North Carolina, Minnesota and Wyoming. Utah, South Carolina, and Louisiana have more than 1,000 to each physician. On the other hand, the District of Columbia has but 325 inhabitants to each physician; California has only 392 people to go around to each doctor; Colorado, only 462; and Vermont, 477. In the case of California and Colorado, their reputation as health resorts evidently accounts for their surplus of physicians. Besides their normal number they have those from all parts of the country whose health requires their residence in an equable climate.

Among others of the States there are a number of surprises in the mode of distribution of physicians. Kansas, for instance, has one doctor for every 510 of population. Indiana comes next with one to every 519 inhabitants. Then Ohio with one to 529; Missouri, with one to 543; Iowa, with one to 562, Arkansas, one to 569; Massachusetts and Michigan, one to 575, Illinois, one to 583, and New York one to 596.

Prof. Thwing of Western Reserve University said not long ago that there was only one profession at present open to young men in which they could expect to make their living from the very beginning of their professional career. This is dentistry. According to the census figures, there is only one dentist to every 10,000 of population. Like the physicians they are thickest at the Capitol. There is in Washington, D. C., one dentist for every 1,250 inhabitants. Health reasons disturb the normal equilibrium of dentist distribution, as it does that of the physicians, and so California has one dentist to every 1,500 inhabitants. Massachusetts comes next in its support of the dental fraternity, about every 2,000 inhabitants providing a living for a dentist. New Hampshire, Vermont, Oregon, Illinois, Connecticut, Ohio and New York follow closely on Massachusetts in this respect.

For physicians it is evident that we have nearly reached the limit of professional numbers as far as medicine can be practised with due hope of economic success. It is evident, too, that the ranks of the dentist are rapidly filling up and that even now there are many places, especially in the more thickly-populated districts, where a dentist cannot expect to make a living for several years after he hangs out his sign.

ECHOES AND NEWS.

NEW YORK.

No More Consumptives for St. Luke's.—Current talk around St. Luke's Hospital is that the department for the treatment of consumptives at that institution, comprising fory-two beds for men and women patients, is about to be abandoned. The reason given in the gossip is that the hospital has no special advantages for treating this disease, and that the wards are so close to those for the general run of patients that there is grave danger of infection. No definite action can be taken until the next meeting of the Board of Trustees on the last Monday in September, and that if the subject is not taken up then it may be considered at the annual meeting of the board in October on St. Luke's Day.

Private Smallpox Hospital.—It has been rumored of late that a private hospital for smallpox patients is contemplated, although the project has not met with much approval either from official quarters or among physicians generally. Commenting on the proposition Dr. Cosby stated that if such a hospital were built by private parties it would have to be conducted under the supervision of the Health Department. He estimated that it would cost not less than $75,000 to put up the building, while the annual expenses would be about $25,000, which he said would hardly pay, as the disease fluctuates in regular periods, being most prevalent every five years.

Campaign Against Mosquitoes.—Should the kerosene campaign which Dr. A. H. Doty, Health Officer of the Port of New York, has inaugurated against the mosquitoes of Staten Island prove satisfactory, a general crusade against all the mosquito grounds in Greater New York may be started under the direction of the New York Board of Health. Commissioner Sexton has the question now under consideration.

Annihilating the Staten Island Mosquito.—Dr. Doty, Health Officer of the Port, has commenced war against the mosquito in this locality. Work on the district he has laid out for treatment, extending from the Narrows to New Dorp Lane, on the island, was somewhat delayed, as the apparatus for distributing oil was not ready. President Sexton of the Department of Health has assured Dr. Doty of his support, and has detailed men to help him in the work. All the swamps and marshy places in the district mapped out are to be inspected, and the breeding-places of the mosquitoes determined and treated with oil.

Prospect Park Lakes as a Mosquito Breeding-Ground.—The attention of the authorities has recently been called to the presence of a dark green scum which forms on the surface of the lakes in Prospect Park, Brooklyn. It is claimed that this scum forms an excellent breeding-ground for mosquitoes and thereby favors the dissemination of malaria. No action in the matter has yet been taken.

PHILADELPHIA.

A Record at Pennsylvania Hospital.—During the month ending July 28th the Pennsylvania Hospital treated more cases than during any similar period in its history. In the emergency wards 3,257 cases were attended to besides 1,798 cases in the dispensary. For the week ending July 6th the cases numbered 998, the largest day's record being 155.

Epidemic of Anthrax.—Cattle on the mountain near Tyrone are dying from anthrax. More than 20 animals have died and many more have the disease.

Test Oleomargerine Cases.—The Dairy and Food Department of the Department of Agriculture in Pennsylvania is to make test cases of a number of manufacturers of "oleo." The makers claim the right to give their product a trace of color and thus avoid the "full yellow" specified by law. The cases are to be tried in Pittsburg and carried to the Supreme Court in order to settle finally disputed points.

An Unusual Departure in Newspaper Ethics.—Under its new management the Philadelphia *Times* has taken a stand which it is sincerely hoped will be imitated by its contemporaries. The following resolutions passed recently by the Medico-Legal Society of this city are self-explanatory: "*Whereas*, the advertising of abortionists and their drugs, as well as other disreputable secret medicines, has for years been a notorious disgrace to the newspaperdom of this city, an evil seemingly without redress, and, *Whereas*, the Philadelphia *Times* under its new ownership has declared for a high ethical plane, avoiding all sensationalism, while at the same time furnishing 'all the naws that is fit to print,' excluding all medical and other questionable advertisements so as to make it indeed a newspaper fit for the family circle, therefore be it *Resolved* that the Medico-Legal Society of Philadelphia highly approves of the advanced stand taken by the *Times* and urges upon the medical profession generally its active support in aiding to carry out that journal's elevated ideals."

CHICAGO.

Suppressed Report of Self-Purification of Streams.—Several members of the Sanitary District Board are said to have suppressed reports setting forth the most elaborate scientific proof ever accumulated showing the self-purification of running streams. After having appropriated $2,500 of public funds for the preparation of the report and after having authorized its publication, they are said to have taken steps to keep the subject-matter of the report from being made public. The circumstance was brought to the surface when

President Alexander J. Jones was asked to permit access to the report made by several expert chemists who spent months making an examination of the waters of the drainage canal and the Illinois River. The experts are Prof. E. O. Jordan of the University of Chicago, Profs. Palmer and Burrill of the University of Illinois, and Prof. Adolph Gehrmann of the city laboratory. Political jealousy, lest the publication should reflect too much credit upon city officials, is alleged to have been the chief motive which actuated the suppression. The suggestion as to this motive comes from officials of the City Health Department. President Jones declares the report was suppressed so the material in it could be used by the Sanitary District in its defense against the attempts of the city of St. Louis to have the drainage canal closed by the courts. Should the report become public, says President Jones, its value as a defense would be injured. The report suppressed is said to show that the waters of the drainage canal are not polluting the waters of the Illinois River and that the alarm of St. Louis is unfounded. Before the waters of the river reach Peoria they are said to be absolutely pure. At that point they are contaminated by the Peoria distilleries. The river again becomes perfectly pure many miles north of the junction with the Mississippi River. Trustees of the Sanitary District are greatly elated over the action of the War Department in issuing orders to allow a swift flow of water through the canal during eight hours of the day. The hours specified are between 4 p.m., and midnight and the flow allowed is 300,000 cubic feet a minute, instead of 200,000 cubic feet, as is allowed during the remainder of the day.

Rush Will Admit Women.—Women hereafter will be admitted to the freshmen and sophomore classes of Rush Medical College. Trustees of the University of Chicago and of the college decided at their last meeting to make them eligible and to admit them to the higher classes also, when additions to the college buildings make that possible. The demand for medical instruction from women who wish to become trained nurses is one of the reasons for the change. Another change announced is the rejection in the medical college of the system of quarters upon which the university is founded.

Sell Ice Without License.—Police have been ordered to arrest ice peddlers who have not obtained a license. Secretary Pritchard of the Health Department has discovered that in the crowded district there is a nomadic lot of delivery wagons which peddle ice without securing the necessary permission. As the health authorities have no means to make tests of their product as to its purity, the sale of ice in this way is held to be extremely dangerous. In many cases the ice is totally unfit for use.

Asylum Is Crowded.—Members of the County Board have been appealed to by President Hanberg to provide additional accommodations for the inmates of the Dunning Asylum. He reported the institution as badly overcrowded and informed the Board that an addition, equipped for the housing of 200 of the feeble-minded wards of the county at an early date, is imperative. The communication shows that there are more than 1,600 inmates of the asylum. The wards are crowded so that many of the unfortunates must sleep on the floors, and, while nothing can be done toward providing funds for an addition before the first of the year, President Hanberg desires that the improvement be taken up in committee and plans made which may be carried out without delay as soon as an appropriation can be voted after the first of the year. It is estimated that the proposed addition will cost not less than $40,000. It has long been needed and President Hanberg says cannot be longer delayed if the county is to continue to care properly for the unfortunates dependent upon it.

Addition to Cook County Hospital.—An addition to the County Hospital is also under consideration and must be passed upon by the County Board before the first of the year. There is urgent demand for two more wards. At present there is no adequate provision for the care of patients suffering from skin diseases. Within the year $25,000 will have to be set aside for this purpose if the standard of the public service demanded of the hospital is maintained.

Milk to Be Confiscated.—Confiscation of shipments of milk is to be resorted to by the Health Department when it is found that the milk has been adulterated. It has been learned that the dealers in Chicago are not to blame in every case in which impure milk is found, but that there are shippers who put in formalin to preserve it. In some cases the dealer is ignorant of this and in others it is put in with his full knowledge. What the health officials have determined to do is to inspect the milk at the depot platforms and when the milk is found to be adulterated it will be emptied out on the track. In pursuing this course the Health Department has the hearty support of the Milk Shippers' Union. Secretary Farmer of that association said that he had investigated some cases where it was found that shippers used formalin. One shipper, he said, sold cream and milk either with or without formalin as ordered. Others put it in and the dealer who was fined was ignorant of the fact. In most cases, he says, these shippers are what are known as "scalpers." They are in the habit of buying up milk for creameries and when there is a scarcity in Chicago and the market is better than at the creameries they ship it here.

Typhoid in Lake Baths.—Typhoid fever is on the increase in Chicago, and the health offi-

cials are inclined to trace it directly to the bathing beaches which have been opened lately and to the recent rains. Chief Medical Inspector Herman Spalding of the Health Department of the city issued a warning to parents that, unless greater care was used by those children who visit the bathing beaches, the city would be in the throes of a typhoid-fever epidemic. There has been a marked increase in the number of cases of typhoid fever during the last days.

Increase in River Wards.—Dr. Spalding says that this indicates a remarkable increase, and the greater number of these cases are in the river wards, such as the Ninth, Tenth, Eleventh, Eighteenth and Nineteenth. He says that the wards where the children who patronize the bathing beaches on the south shore live are also showing a large increase in fever patients. "It is due to the bathing to a large extent," said Dr. Spalding. "I do not want to argue against bathing, because that is a very necessary thing for the health of the community; but the trouble is that boys and girls, and even men, who ought to know better, go into the lake and swallow the water while swimming. This water is polluted. Our experiments show that a rainfall of less than a quarter of an inch is sufficient to pollute the water of the lake along the shore, and every day you will see men on the pier dip up water from the lake and drink it. This is poisonous and results in typhoid fever in many cases. Even if those who bathe in the lake are careful not to take any of the water into their mouths while in the lake, they will wipe their lips with wet hands, which is equally as bad as taking the water into their mouths."

Tuberculosis.—Following the discussions at the recent Congress of Tuberculosis in London on the cure and possible eradication of the disease, the *London Sphere* has compiled a record of deaths in the world's largest cities which shows that Chicago has the lowest mortality rate from the diseae and Buda-pesth the highest.

GENERAL.

New Jersey Insane Asylum Investigation.—The investigation into the charges recently brought against the management of the State Asylum for the Insane is taking place in the presence of Gov. Voorhees, who nad been requested to attend. Dr. Baldwin, B. W. Andrews, and Judge Joseph Thompson, the three members of the hospital Board of Management, comprise the investigating committee. When the proceedings opened they announced that no allegations beyond those contained in the recent complaint of hospital attendants concerning the alleged inedible and insufficient food supplied to them would be considered by the committee. Other allegations, involving indiscretions, neglect, and mismanagement of both the patients and the business end of the institution are thus barred from the examination at this time.

New Hospital for Crippled Children.—A. C. Burrage of Boston has leased Bumkin's Island from Harvard University for 399 years, and will build a hospital on it, and make it a free summer home for the crippled children of Boston. The island is near Hull. It was given to Harvard College by Samuel Ward, who was a friend of John Harvard. The terms of Ward's will were such that the land could not be sold outright.

Transfer in Marine Hospital Service.—Surgeon Kinyoun, recently of San Francisco and now in charge of the Marine Hospital at Detroit, has been detailed to visit Japan and China to inspect the work of the Marine Hospital Service with special reference to the plague. Dr. Kinyoun was one of the Marine Hospital experts who was abused by San Franciscans for saying there were plague cases in "Chinatown."

University of California Appointment.—Dr. Archibald R. Ward of Ithaca, N. Y., has been appointed veterinarian of the Agricultural College of the University of California, a new position created by the Board of Regents. His work will be closely associated with that of Leroy Anderson, head of the Dairy School, buildings for which are now in course of construction.

Retirement of Surgeon-General of Navy.—The term of Surgeon-General W. K. Van Reypen, Chief of the Bureau of Medicine and Surgery in the Navy Department, will expire December 18th. Dr. Van Reypen will be retired from service in November, 1902, under the law. His services during and since the Spanish war undoubtedly will secure for him a reappointment to the head of the bureau, and that reappointment will assure to him retirement with the rank and pay of a Rear Admiral. What the officers of the Medical Corps are interested in is what will become of the office after Dr. Van Reypen has been put on the retired list. After his retirement there will be available several medical directors, whose terms are approaching completion, and it is thought the President may choose one of these, and thus give to the fortunate man the chance to retire with the highest rank. But it is also suggested that the President may overlook the medical directors and select a Medical Inspector for the place.

Sir William MacCormac on Wounds and Warfare.—The President of the Royal College of Surgeons, Sir William MacCormac, read a paper before the British Medical Association, recently in session at Cheltenham. He pointed out that the character of gunshot wounds had completely changed since his experiences in the Franco-Prussian war (when he was Surgeon-in-Chief to the Anglo-American ambulance). Not only was the severity of the

wounds diminished, but they were also less frequent; so the improvement made in weapons did not render the prosecution of war more difficult, as contended in some quarters. Only 6 per cent. of the wounded died.

Antisepsis on the Field of Honor.—This seems a year of odd duels in France, as it is also a year of other odd things there. The strangest encounter of all on the field of honor was that of Ernest Daudet, for whose moral guidance his father wrote "Sapho," and a journalist named Gérault Richard. It is stated that after the first attack, the point of Daudet's sword accidentally touched the ground, when the seconds intervened and stopped the contest until the blade could be disinfected. Afterward Daudet was wounded in the wrist, but, thanks to the antiseptic precautions taken by the seconds in this duel, which doubtless establishes a precedent, he is doing well, and will soon be able to use his sword arm again in defense of his honor.

Sir James Paget's Memoirs and Letters.—It seems that Sir James Paget, F.R.S., who died a few months ago and was honored with a memorial service in Westminster Abbey, left the manuscript of a work of "Memoirs and Letters" now in active preparation for publication under the editorship of one of the distinguished surgeon's sons, Stephen Paget. Although the Paget family is connected with several American families by marriage, undoubtedly the chief interest in the forthcoming publication will lie in the fact that the late Sir James included in his circle of patients and intimate friends some of the most conspicuous personages in the United Kingdom. The King and Queen were among his patients, as was Queen Victoria before them. His student days were passed at St. Bartholomew's Hospital, and he began to practise in 1857. We are looking forward with much eagerness to the publication of these letters which are sure to reflect the brilliant personality of a distinguished medical man.

No Secret Medicines Sold in Austria.—Carl Bailey Hurst, United States Consul General at Vienna, Austria, in a recent report to the State Department says, among other things:

"In consequence of many inquiries addressed to this Consulate General in the matter of the Government regulations in Austria regarding the importation and sale of patented medicinal and chemical preparations, I would report that the sale of 'arcana,' or secret remedies, has always been strictly forbidden in this monarchy. Trade in such medicines and advertisements of the same are under strict surveillance of the law. Further, those medicinal preparations of which the prescriptions are not open to inspection by physicians, or in the prescription of which the substance of the medicinal ingredients cannot be definitely recognized as to kind and quantity, may not be kept for sale in apothecaries. Only those manufactures may be considered as pharmaceutical specialties that contain drugs acknowledged to be medicinal remedies, as, for instance, balsam copaiba, oleum santali, and the like.

"Every new medicinal preparation intended for use by the public must be reported to the authorities, and its sale may not be begun until said authorities have found no reason to prohibit the same. Prescriptions of foreign medicines must be accompanied by precise directions for their preparation from the foreign manufacturer, and be provided with his signature and business stamp. Altogether excluded are cosmetics that by their labels, wrappers, and advertisements are affirmed to be efficacious in the removal of personal blemishes—impure skin, freckles, liver spots, and baldness—and are, therefore, qualified as remedies.

"The regulations in Austria in regard to the advertisement of patent medicines are likewise strict. All laudatory notices in local publications of cures and remedies coming from abroad constitute a transgression of the trade laws, and, under certain circumstances, foundation for complaint of unlicensed medical practice."

Consul Hossfeld of Trieste transmits, under date of July 12th, a report covering the same information. He adds:

"The Austrian law also undertakes to regulate the prices to be charged for patent medicines, for it provides that whenever the reasonableness of the price of such a remedy is questioned, it shall be rated on the basis of the official tariff promulgated in the Pharmacopœia Austriaca.

"Those of our manufacturing chemists who are disposed to take the Austrian public or sanitary authorities into their confidence will probably not find it very difficult to obtain the necesary permission for the sale of their products, but I doubt whether any business which they may do in this country will ever prove a source of great profit to them."

American Association of Obstetricians and Gynecologists.—This Association will hold its fourteenth annual meeting at the Hotel Hollenden, Cleveland, O., Tuesday, Wednesday and Thursday, September 17, 18 and 19, 1901, under the presidency of Dr. William E. D. Davis, of Birmingham, Ala. The committee of arrangements is composed of Dr. M. Rosenwasser, 722 Woodland Avenue and Dr. William H. Humiston, 122 Euclid Avenue, Cleveland, either of whom may be addressed concerning rooms or other local information regarding the meeting.

The following list of papers is offered:

The President's Address, William E. B. Davis, Birmingham; Indications for the Combined Vagino-Abdominal Operation of Hysterectomy, Rufus B. Hall, Cincinnati; A.

Method for Suspension of the Uterus, Robert T. Morris, New York; Tuberculous Peritonitis, Experimental and Clinical, John B. Murphy, Chicago; Report of a Case of Acute Pancreatitis and Fat Necrosis, Edward J. Ill, Newark; Pelvic and Abdominal Tumors Complicating Pregnancy, with Report of Cases, Rufus B. Hall, Cincinnati; Pathology and Treatment of Hourglass Stomach, with Report of Two Cases, Charles G. Cumston, Boston; Early Operations in Appendicitis and Method, Joseph Price, Philadelphia; The Undeveloped Uterus, C. L. Bonifield, Cincinnati; An Interesting Case of Tubo-Abdominal Pregnancy, Wm. H. Humiston, Cleveland; Report of a Case of Ruptured Tubal Pregnancy, Webb J. Kelly, Galion, O.; Diseases and Injuries of the Cervix Uteri and Their Treatment, Joel W. Hyde, Brooklyn; Extra-uterine Pregnancy; Report of Cases with Specimens, George S. Peck, Youngstown; Is Cæsarean Section Justifiable in Placenta Previa? E. Gustav Zinke, Cincinnati; Some Reflections on Ectopic Gestation, David Tod Gilliam, Columbus; Some Forms of Disease Involving the Uterine Appendages, Augustus P. Clarke, Cambridge; The Mechanical, or Combined Plastic and Mechanical Treatment of Retrodeviations of the Womb, M. Rosenwasser, Cleveland; A New Method of Opening the Abdomen in Gynecological Surgery, Charles G. Cumston, Boston; A Second Contribution to the Surgery of Gastric Ulcer, Henry Howitt, Guelph, Ont.; Indications, Technic, and Remote Results of Salpingostomy and of Resection and Ignipuncture of the Ovaries, with Tables of 104 Cases.

Obituary.—Dr. Henry Armgardt of 370 Leonard Street, Brooklyn, died in Harzburg, Germany, on July 31, 1901. He was fifty-two years of age. He began the practice of medicine in Chicago and later moved to New York city and finally to Brooklyn, where he practised continuously until he sailed for Europe on June 15th last. He was a Professor in the Eclectic Medical College of New York city. He was also a Freemason and a member of the Royal Arcanum.

Dr. Stephen Foss died at his residence, 15 Cornelia Street, Brooklyn, on August 1, 1901, aged 76 years. Dr. Foss was born in Portland, Me., and graduated from the Medical Department of Harvard University. He successfully practised in Brooklyn for many years, but about five years ago retired on account of blindness. He was a veteran of the War of the Rebellion and formerly a member of Warren Post, G. A. R.

Dr. Frank B. Bingham of Buffalo was killed shortly after noon August 2d, by a trolley car at Main and Summer Streets. Dr. Bingham was riding his wheel at the time.

Dr. James V. Kendall, one of the oldest surgeons of Central New York, died this week at his home in Baldwinsville, Onondaga County, N. Y. He was eighty-three years old, and had been surgeon of the 149th New York Volunteers. He was a member of the Assembly in 1869 and active in Republican politics.

Dr. Henry Buckingham Horlebeck, a former President of the American Public Health Association, and for twenty years the Health Officer of Charleston, N. C., died in that city early Friday morning. He was stricken with paralysis several months ago. Dr. Horlebeck was an authority on yellow fever. In his will he left instructions to have his body cremated and the ashes buried there. The body was shipped to a Staten Island crematory.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

LONDON, July 27, 1901.

THE TUBERCULOSIS CONGRESS—A QUARREL AMONG THE GERMANS—A SCRAMBLE FOR PRESENTATION TO THE KING—KOCH AND HIS MEDAL—HIS SENSATIONAL UTTERANCE ON TUBERCULOUS MILK AND MEAT—VIRCHOW'S CRITICISM—RESOLUTIONS PASSED BY THE CONGRESS—ENTERTAINMENTS—AN EXPECTED SHOWER OF HONORS.

As I write the last echoes of the Tuberculosis Congress are dying away. The general impression is that the meeting has been a brilliant success. The attendance has been close on 2,000; almost every civilized government has been represented, and quite a crowd of more or less distinguished foreigners has added liveliness to the normal dulness of a British meeting. With one exception there has been no communication of an epoch-making character, but much solid work has been done in the various sections. The general press has given a considerable amount of space to reports of the proceedings, and has discussed the facts and proposals brought forward with a sense of their importance which is as novel as it is gratifying in English journals where medical matters are mostly totally neglected or treated as esoteric mysteries that concern only the doctors.

There was a hitch at the outset which, if it had not been set right, might have gone some way to imperil the success of the Congress. In Germany, and indeed on the Continent generally professional jealousies, if they do not run higher than among us, at least find more outspoken expression. In most German universities, as every one knows, there exists a system of dual professorship in the different branches of medical science which is admirably adapted to create jealousy and anger in the most celestial souls. Hence it is a general rule, to which there is hardly an exception, that the two professors, say of surgery, hate and despise each other and refer to each other in their lectures in the most contemptuous terms, to the delight and edification of the students. At Berlin Professors Gerhardt and von Leyden are the great Panjan-

drums of medicine, but like Society "lions" each when he hears his rival roaring thinks him a bore. The German leaders are in the habit of going to Congresses like the Highland Chiefs of old, "with their tails on," that is to say, with a bodyguard of devoted adherents who form a *claque* for them wherever they go. The Gerhardt and Leyden parties fell out on the first day of the Congress over some trumpery question as to the choice of a speaker on some ceremonial occasion. Like the Irish Members of the House of Commons at the time of the Parnell split, the discordant Teutons got a room for themselves in which to fight out their quarrel. When this matter was arranged, another row disturbed the philosophic calm of the Germanic mind. This time it was because some one who thought he should have had a place in the second row was relegated in the third. Such harmony is in immortal souls!

Another incident delightfully illustrative of the large-mindedness of the paragon of animals, man, occurred toward the end of the Congress. The King had been approached by some one who has the Royal ear with a suggestion that he should receive a certain number of the more prominent among the foreign members. His Majesty whose days are passed at present in decorating the British Army, intimated that this addition to his labors would bore him exceedingly. The proposal was therefore abandoned—rather to the relief of those on whom the delicate duty of selecting the persons to enjoy the beatific vision of Royalty would have devolved. But princes are proverbially fickle, and Edward the Seventh seems to have taken counsel with himself, and, probably feeling that as patron of the Congress it behooved him to do something to show an appearance of interest in it, determined to be on view to some of its members. The result was that late one afternoon he sent Sir William Broadbent, his physician in ordinary, a message that he would receive a batch of distinguished foreigners on the next day. When the news got abroad, Sir William Broadbent's door was besieged by a horde of excited representatives of various nationalities, each urging his claims to be presented. Not only physicians but Ambassadors crowded Sir William Broadbent's house, representing that if this or that official person were not included in the list there would be all sorts of international complications. How the conflicting claims were finally adjusted I do not know, but I have no doubt that Sir William Broadbent, who is a harmless sort of person, has innocently made a number of deadly enemies. One (officially) distinguished German, was, it appears, nowhere to be found. Every hotel in London was ransacked to find him, as it was impressed on those responsible for the selection of the elect to whom Royalty was to manifest itself that the most fearful consequences would follow if this particular official were not presented. He was found at last in some obscure lodging, sulking like Achilles in his tent, because as he fancied he had not been asked. It was with some difficulty that he was appeased and induced to honor the king of England by allowing himself to be presented to him.

Koch was not among those presented, but that appears to have been his own fault. He chose to go to a meeting of the British Institute of Public Health, to receive a medal which he thought he was to get from the hands of Lister. He was in blissful ignorance of the true status of the Institute in question which rightly or wrongly is not regarded with any particular favor by the medical profession. The distinction bestowed on Koch is not therefore looked upon here as of any great value. Koch appears to have discovered this for himself, for he went to Eastbourne where the meeting of the Institute of Public Health was being held by an afternoon train and returned to London by the next, having shed the luster of his countenance on the meeting for about a couple of hours.

The great sensation of the Congress has been Koch's denial of the infective power of bovine tuberculosis in man which has made all our butchers and farmers rejoice exceedingly. Its effect on the Congress can only be compared to that of a dynamite explosion. The airy way in which Koch asked the medical world to receive a new doctrine erected on the flimsiest basis of fact is a remarkable illustration of the degeneration which has overtaken one of the greatest scientific investigators of our time. It is too clear that success has turned his head, and that he cares more for "staggering" than for instructing humanity. His startling declaration that precautions against the use of tuberculous milk and meat are useless was delivered with the calm assurance of an infallible pope promulgating a dogma which the faithful are to receive on pain of damnation. His views were severely criticized by Lord Lister who was in the chair. Lister is the most courteous of men, and it is unusual for a chairman to criticize the utterances of a speaker whose sponsor he is for the occasion. But Lister criticized Koch very sharply, and he was greatly annoyed that he was represented in the newspapers as accepting his doctrine. Professor Nocard, the great veterinary authority who spoke afterward, contrived with the art of a consumate actor to overwhelm Koch with compliments, while conveying plainly to such of the audience as understood him that he considered the sensational statements of the inventor of the famous *Mittel* (which by the way he was induced to reveal is made from bacilli of human origin) not mistakes but deliberate lies!

Koch's views find little or no acceptance among English men of science, and they are almost universally rejected by his own countrymen. It is even insinuated that he and Professor Bernhard Fränkel are simply put forward as the exponents of the German Government and Agrarian party for some purposes of their own. Professor Virchow is reported to have said in an interview published by the Berlin *Lokal Anzeiger:* "I have combated for years the view of the hereditary transmission of tuberculosis, but for the rest I do not agree with Dr. Koch, and at the last meeting of

the Medical Society I spoke most strongly against Dr. Koch's deductions. Dr. Koch is not Rome and the last word has not been spoken." Of course this deliverance must be taken subject to discount as being that of a rival oracle. Virchow has ever since the days of the tuberculin boom lost no opportunity of expressing his disagreement with Koch's work.

Among the resolutions passed at the closing meeting of the Congress yesterday was one which had direct reference to Koch's new teaching. It was to the following effect: "That, in the opinion of this Congress, medical officers of health must use all the powers at their disposal and relax no effort to prevent the spread of tuberculosis by milk or meat." On the suggestion of Dr. Herron (whose guest, it may be mentioned in passing, Koch is), strongly supported by Dr. Farquharson, M.P., an addition was made to the resolution asking for an immediate official experimental inquiry into the identity of bovine and human tuberculosis. A summary of the other resolutions must suffice. Mr. Malcolm Morris, General Secretary of the Congress, moved that "Tuberculosis sputum is the main agent in the conveyance of the virus of tuberculosis from man to man, and indiscriminate spitting ought therefore to be suppressed." Mr. Harold Swithinbank endorsed these views, and called upon municipality in this country to follow the rational policy adopted in New York, the chief Canadian cities, Sydney, and other places, by making the practice a penal offense. To this succeeded a motion by Professor Sims Woodhead of Cambridge and Sir William Broadbent, "That, in the opinion of this Congress, all public hospitals and dispensaries should present every patient with a leaflet on the prevention of consumption and should supply and insist upon the use of a pocket spittoon." A third motion ran "That voluntary notification of cases of phthisis, when accompanied by expectoration, has been attended with success and should be encouraged wherever the means exist to take the necessary consequent measures." Dr. Niven of Manchester showed that excellent results have followed in Brighton, Manchester and Sheffield, where such notifications exist. Cases were discovered early, and disease arrested. Professor Clifford Allbutt strongly approved of beginning the required reform in this way—voluntarily. On the proposal of Sir James Burdon-Sanderson, Bart., Regius Professor of Medicine at Oxford, and Sir R. Douglas Powell, it was agreed "That the provision of sanatoria is indispensable among the measures necessary for the diminution of tuberculosis," especial reference being made to industrial centers. Another resolution proposed the establishment of a permanent international committee to keep the public everywhere informed of the progress made and the measures adopted to combat tuberculous disease; while Professor Crookshank and Dr. Theodore Williams affirmed that the overcrowded, dark, ill-ventilated dwellings and insanitary conditions of the working classes favored the spread of contagion. Professor Brouardel and Professor Calmette obtained a vote in favor of antituberculous dispensaries, to which the working classes could repair for assistance at the very beginning of the disease. Finally, the Congress, at the instance of Professor Robin and Sir Wlliam Broadbent, suggested that for the next meeting of this kind inquiry should be made into the predisposition of individuals to forms of tuberculous disease. These resolutions all of which here passed unanimously may be taken as embodying in themselves the substance of the work of the Congress.

The entertainments in connection with the Congress have been as successful as the scientific proceedings except during the last two days when a tremendous thunderstorm followed by cataracts of rain turned the town into a flooded sewer and the country into a swamp. This necessarily ruined many of the out-door functions—garden parties, excursions, etc.. The greatest entertainment of all, however, is yet to come. This is a grand pyrotechnic display which will take the form of a shower of honors and decorations. Every one who has had anything to do with organizing the Congress expects to be made a Knight at least. In such circumstances it is most prudent to treat oneself on the non-expectant method embodied in the ninth Beatitude: "Blessed are they which expect not, for they shall not be disappointed."

SOCIETY PROCEEDINGS.

BRITISH MEDICAL ASSOCIATION.

Sixty-Ninth Annual Meeting, Held at Cheltenham, July 30, 1901.

FIRST DAY—JULY 30, 1901.

President's Address.—Dr. George Bagot Ferguson read an address on "Scientific Research as the Indispensable Basis of All Medical and Material Progress." He first welcomed the visitors to Cheltenham and spoke of its location, its reputation as a health resort, gained by reason of the saline springs that abound in the neighborhood, and also referred to the medical men of the district who had become more or less famous. He then took up the subject in hand.

The Foundations of Medicine.—"*Homo sum, humani nihil a me alienum puto,*" and this sentence of Terence may well be taken as descriptive of the modern practitioner of medicine. Is there nothing revolting in medical and surgical training and practice, in the year of dissection so wisely exacted from every medical student, in the indispensable work of the deadhouse, in the examination of patients, and in many operations of surgery and obstetrics? There is much, no doubt, repulsive at first in our professional education, but the cheering thought of doing service to common humanity

removes the feeling of abhorrence that would otherwise overcome us. As we for others, so others willingly for us; for sooner or later the medical man himself must seek the help of his fellows. Age, infirmity, mortal illness must come to him too in his turn, and so during his days of activity he must shrink from nothing which is repulsive and hesitate at nothing which is disagreeable, if only he may know more fully and act more precisely. *"Homo sum, humani nihil a me alienum puto,"* is the most inspiriting and the most comforting of mottoes.

Man's body is our chief care and study, its anatomy, its physiology, its diseases and injuries. Of anatomy we may say that it is the indispensable basis of medicine and surgery, and it can be honestly stated that there never was a conspicuously successful practitioner who was not a good anatomist. To the younger members of the profession it should be said, Never lose your grasp of anatomy, dissect whenever you have the opportunity, and as regards your anatomical manuals *"Nocturnâ versate manu, versate diurnâ."* Physiology teaches us that which is in accordance with Nature, and if we would recognize that which is abnormal or diseased, that which is pathological or contrary to Nature, it follows that we must ever keep before our eyes the physiological standard, the normal processes, reactions, and chemistry of the human body. Then of diseases themselves or variations from the normal we may recognize that many are essentially derangements of function, such as catarrh, anemia, diabetes, gout; whilst others are due to true anatomical changes, such as chronic Bright's disease, atheroma, hemiplegia, valvular disease of the heart, and cirrhosis of the liver. Others, again, like anthrax, phthisis, glanders, typhoid, tetanus, and diphtheria are due to parasitic invasion. Indeed a division of diseases may be made into anatomical, physiological, and parasitic; the last including tumors, of which the malignant or infective are especially parasitic. Degenerating from their high pkosition in the scale of being, some of our connective tissue or endothelial or epithelial cells, as the result of malnutrition (as Sangalli asserts), or of irritation, or under the influence at first of some specific organism (some blastomycete) as Thoma, Scheurlen, Korotneff, Russell, Sanfelice, and Roncali have asserted, comport themselves somewhat as the yeast fungus, itself a blastomycete, in a suitable medium would do, growing ever and working never (as Adami suggests), and soon, unless the surgeon interposes quickly and boldly and removes root and branch the malefic colony, the whole body becomes contaminated by the animal fungoid, which soon destroys its life. However numerous the departments of medical science may be—and we have thirteen represented at this meeting—anatomy, physiology, and pathology, being the true foundations of medicine, should always occupy a very large share of our attention.

One Hundred Years Ago.—Dr. Ferguson then dwelt upon some of the medical workers of the past two centuries, sketching in brief the salient truths brought out by these masters of medicine.

Scientific Research and the Present Medical Standpoint.—He said that in looking over the important facts in medicine that stand out through the century one is struck by the fact that the so-called practical man is never heard of, but that the biological dreamer is the man who has made most of the lasting discoveries. It is true that the practical man is indispensable, but he is not like the great biologist. The cell theory, for example, lies at the very foundation of modern medicine, and this theory certainly originated entirely with the biologists. The cell nucleus was actually seen and drawn by F. Bauer as long ago as 1802, though it was not before 1831 that it received that name from Robert Brown, the botanist. Little notice, however, was taken of the subject before the publication of Schleiden's paper on Phytogenesis in *Müller's Archives* for 1838, in which he asserted that "every plant is an aggregate of individualized, independent, separate beings—namely, cells." Theodor Schwann, also in the next year, made a similar assertion regarding animals in his *Microscopical Researches,* of which, and of Schleiden's paper also, the Sydenham Society published a translation in 1847.

Next came Hugo von Mohl in 1846, who recognized what we now call protoplasm in the cells of plants; the identity of which with a similar substance in the cells of animals was soon afterwards proved by Cohn and Remak. To Schwann a cell without a wall and a nucleus was no true cell, but Leydig in 1856 adduced pus and mucus corpuscles as instances of wall-less cells, and so step by step the ground was cleared for the now historical cellular pathology of Virchow, which influenced so profoundly the medical thought and practice of forty-three years ago. To Virchow as to Schwann a cell wall was a necessity, though this idea was soon afterwards dispelled by Lionel Beale and independently by Max Schultze in 1861. To Max Schultze we owe not only the extension of the term protoplasm (the bioplasm or living matter of Beale) to the contents of animal cells also, but the best description of an animal cell, namely, that it is a protoplasmic mass containing a nucleus; though even this last, we may add, is non-essential. All this work on the cell theory gave the original inspiration to Pasteur, and Pasteur leads up to Lister, of whom it is not necessary to speak, for he needs no speech, though he might well say of himself, *Quæ regio in terris nostri non plena laboris?*

Bacteriology, roentgen ray work, the study of antitoxins, animal extracts, ophthalmology, the advances in scientific chemistry and in the

study of parasitic diseases, in turn were discussed and their futures suggested.

More Universities and Research Institutions Needed.—The progress of pure science means medical progress also, and that it is to the men of pure science that we must still look to hold aloft for us the torch of progress. It is to be hoped that in the great advances still to be made Great Britain and Ireland may play their worthy part; but this will not be unless some improvements are made in their educational arrangements. As the result of several recent Augusts spent in many of the Continental capitals, he had been struck with the thoroughness and scientific spirit everywhere there manifested; being very different from the antiscientific spirit which characterizes most of the wealthier and more cultivated classes in this country. This antiscientific spirit is only eradicable by the better education of the young. To what other cause can we ascribe the fact that although the aniline dyes were discovered in 1858 by an Englishman, Dr. W. H. Perkin, yet almost the whole of their manufacture is now carried on in Germany? The National Physical Laboratory and the Jenner Institute of Preventive Medicine, have been established, the former in principle, the latter in reality, thanks to the splendid munificence of Lord Iveagh. New colleges, universities, and technical schools have been started, and some 15 to 17 research scholars are appointed every year, one-half of whom proceed at once to Germany to make their researches! What has been done, however, is as nothing to what ought to be done. The defences of the empire must not be overlooked, but of what avail will be those defences, if trade is gradually lost, for want of exacter knowledge? For trade and medical progress, and those very defences themselves, rest entirely upon progressive science.

But the cost? It would be as nothing in proportion to the gain, and a Faraday, a Koch, or a Pasteur would be a cheap purchase at a million. Whereas France, Germany, and the United States educate at their universities approximately one student in every 1,500 of the population, we in the United Kingdom are content with less than 1 in 2,000. Whereas Germany spends £753,000 a year on its twenty-two universities and France £740,000 a year on its sixteen, Great Britain and Ireland are content with less than one-fifth of that amount, namely, £135,339 among seven of their thirteen. Although the Leland Stanford, Jr., University of California has received no less than nine millions sterling from private munificence, and many others of the 480 American universities and colleges have likewise received huge sums—the Chicago University £2,000,000, the Johns Hopkins University £1,400,000 and the Cornell University over £1,000,000—no such general largesse is to be expected from British millionaires. The help must come from Government, supplemented by local contributions, or it may not come at all. Yet the matter is one of life or death for the country, for more and more every year the victory in every department, and the predominance in arts and trades, will pass to the possessors of the latest knowledge, the deepest science, and the most perfect and most economical processes. It cannot but be believed that this great need will soon be remedied, and that at the cost of a few battleships real universities of teaching and research, like the new University of Birmingham, will be established in every large town, and technical and research institutions—there are twenty-five of these in Germany and forty-three in America—in most of the smaller ones. At present we are feeling keenly the competition of America, a competition that is not likely to diminish, for it possesses over 100 schools of chemistry, and has 10,000 students of engineering. This competition we can only hope to resist by imitating the foresight, generosity, and enthusiasm for science of the American Governments and of the American men of wealth. Examinations are of secondary consequence. China is the most examined country in the world, and look at it. Original work done under the professor's eye and at his suggestion is far better than any examinations, and the true ideal of a real university must always be in the words of Paulsen, "True knowledge from free research." Let us hope that we shall not have long to wait for many such universities, where the best and most practical scientific education will be open to all at low cost, as in the University of Michigan, where the fees do not exceed £7 a year, or at no cost at all, as in the State of Massachusetts, and in many of the Western States of America. It is not trades' unions and skilled workmen that can insure the continued prosperity of a nation, but the trained intelligences that direct its energy; and we may rest assured that whichever nation shall elevate highest the general standard of education will be the nation which will lead the world. Since the preceding section was written I have to record the magnificent generosity of Mr. Andrew Carnegie, with his gift of £2,000,000 to the Scottish Universities, one portion of it to be applied mainly to the teaching and endowment of research, and the rest to replace the fees hitherto paid by their students. Happy Scotland! that not only receives about one-third of the whole parliamentary grant for university education, but has found besides such a princely and far-seeing benefactor as Mr. Andrew Carnegie.

Aspiration, Ethics, and Conclusion.—And now for a few concluding words about the aims, the aspirations, and the ethics of the profession. After a long and expensive education, after knowledge acquired laboriously and at great personal risk (the clergyman's death-rate is 16 per 1,000, the lawyer's 20, and

the doctor's 25) the medical man must not hold himself too cheaply. He is the heir of a long tradition, originating from the sages of India and from the temples of Greece. Our health and happiness are in his hands and the issues of life and death tremble often upon his judgment. So he must bear himself with confidence and proper pride, remembering his great traditions and the antiquity of his calling, which ranks next to that of priest. He is worthy of his hire, and that hire should be such that in the day of his popularity he may make due provision for his age and retirement and for those whom he will leave behind him. He must work hard and read and think all the days of his practising, for the best practice of to-day will not be that of even five years hence. His aspirations must be for the very best in each department of practice, for the progressive advancement of his art, and for the increased dignity and consideration of his calling.

Above all, let him be chary of any commerce with the enemies of science. *Magna est Scientia et prævalebit.* None the less serious is his responsibility who, knowing its benefits, yet retards its progress, or who ignorantly would deny to others what he is insufficiently instructed to understand for himself. Beware of panaceas. There are none in truth, though the worship of Panacea was not confined to Ancient Greece, and is as reprehensible in the cold clear light of twentieth-century science as is the equivalent assumption by too many specialist omniscience.

The wise practitioner will strengthen his position, as he will certainly increase his knowledge by somewhat frequent consultations, and he will do well if, like Hunter and Jenner, he cultivates some extraneous intellectual interest to relax occasionally the stress of his anxious labors. I venture to think that nothing will do him more good than the pursuit of one or other of the arts, or of some branches of biological or physical distraction, be it zoology or botany, electricity or telescopy. The wise practitioner, moreover, will confine his studies within certain limits if he wishes to attain to a thorough knowledge of even some portions of his great subject. He cannot be a universal specialist. The good and worthy practitioner will never be wanting in sympathy. Too often there is physical pain to be relieved, and, thank God, it can be relieved; though at other times the sufferings will be nervous rather than physical; and these are the occasions when sympathy and patience are most needed, though it is not always easy to show the first and to retain the last in the interest of some nervous sufferer on a cold wet night at 3 a.m.! In respect of medical ethics the case is very simple. Treat and think and speak of your brother practitioners as you would wish them to treat, and think, and speak of you. Medical ethics are, indeed, so completely summed up in this single sentence as to make it quite unnecessary for me to say more. With high aims and aspirations, with true ethical, that is to say, brotherly feeling, and with constant consideration for the public weal, we shall each and all be worthy of the well-known description in Chaucer, and be "veray parfit practisours."

Address in Surgery.— Sir William Thomson presented an address on some "Surgical Lessons from the Campaign in South Africa." The weapons of war have been entirely revolutionized during the past fifty years and the advent of the modern small-bore rifle has introduced into military surgery a large number of entirely new problems. The war was essentially a war of small arms; and so far it would seem as if all the improvements in them have not added to their immediate destructiveness. But this conclusion would not be entirely justifiable. The weapons are more accurate and of greater range than have been employed before, and given the same conditions of closer quarters and the formation of troops as formerly, opposed men, armed with breech loaders and using magazines, must inflict terrible damage. We have had some instances of the result in this campaign. What has happened is that we have learned to diminish the effect of the fire by making considerable intervals between the men; so that there is much less damage from loose unaimed firing than if the enemy had huge blocks of human beings for targets. If we add to this the fact that firing begins at a range of 2,000 or 1,500 yards; that the very light bullet is subject to the deflection caused by varying densities of atmosphere and force of wind, all conducing to inaccuracy of shooting, we have some reasons why the efficiency of modern rifle fire under certain conditions has so happily disappointed our anticipations.

The Effect of the Small-Bore Bullet.— When, however, we come to consider the nature of the wounds inflicted by the two classes of weapons the difference is very great; and this depends mainly upon the character of the bullet employed. The old flint lock had a ball nearly seven-tenths of an inch in diameter, the Minie rifle of the Crimean war one of six-tenths, the Enfield of five-tenths, the Martini-Henry of four-tenths, the modern small bore represented by the Lee-Metford is about three-tenths, and the Mauser is a decimal smaller. The bullets in the first group were all of lead, and elongated, with the exception of that of the old musket; the bullets of the second group, however, which may be likened to an inch and a quarter of ordinary lead pencil, are encased in a hard cupro-nickel case, somewhat pointed, polished, and absolutely smooth. The vast majority of wounds received in South Africa were caused by these bullets. It is certain that the enemy used other varieties; some-

times the soft-nosed sporting bullet, which, having an end of exposed lead, spread out on impact and inflicted a lacerated wound. Explosive bullets for big game have been found on prisoners; and the old Martini rifles were used with considerable freedom. In other instances the mantles were split at the top so that they expanded on impact. But it was not always possible to identify the effect as due to a missile contrary to the usages of civilized war. There is a popular belief that an elongated bullet must hit its object practically at right angles if that object is upright when presented to the line of fire. But between the discharge of the bullet and its arrival at the mark, a great many things may happen. It is often deflected in its flight, or it may be turned by clothing or other substances, and make its impact at all sorts of angles, causing large wounds. Sometimes the Mauser bullet has turned completely around and entered base forward. But a great number strike the ground, or a stone, and become much more formidable in their effects. This ricochet produced many kinds of deformities in the bullet; the case was often torn off wholly or in part, and, when the primary contact occurred close to the body spattered the skin about the entrance wound with small fragments of the cupro-nickel mantle. Now and again the exposed lead mushroomed and produced ghastly lacerations. But the result of a bullet striking soft parts sideways after a ricochet often made it difficult to believe that it had not contained a bursting charge.

Wounds of Soft Parts.—The large number of those wounded in the soft parts who recovered was a matter of surprise. This result was due to at least three factors, namely, the bullet itself, the early application of the dressings and the climate. The bullet seems to cleave the tissues rather than tear them apart; the early aseptic dressing and the high temperature and dry air; these were the main causes.

Wounds of Bones.—In the treatment of compound fractures of the femur the lesson that was learned was that conservative treatment gave by far the best results. Amputation of limbs was quite the exception, and was only done when the case was otherwise beyond hope. For the lessons of modern surgery, the vast possibilities of recovery which the teaching of Lister had put within the grasp of every practitioner of the art in the world, had already proved that the nearer we could approach the natural conditions the greater the safety for the patients. Therefore when a bone was broken by a bullet, and there was no other lesion but the track made through unimportant soft parts, the indication was to apply an antiseptic dressing at once, to secure as much immobility as possible, and to have the patient sent to a place where rest and more deliberate attention could be had.

Perforating Wounds of Abdomen.—On the whole, considering the difficulty of diagnosis in many instances at the outset, the fact that intestines may be found unwounded, and if wounded may be occluded by natural processes if not interfered with, it seems that in war as we stand at present the man whose abdomen is perforated by a small-bore bullet has a better chance of life without operation than with it, bearing in mind the circumstances on the field under which laparotomy must be performed. That is an opinion which most surgeons came to when experience had ripened after the early months of the campaign. Although the judgment may be a little humiliating it is one which must for the present be accepted.

Progress Made by Military Surgery.—We have seen a marvelous proportion of recoveries from severe wounds, and we have been able to rejoice at the great reduction of suppurating cases, and the practical absence of such infective diseases as tetanus, erysipelas, pyemia and hospital gangrene. This great difference in the record of to-day as compared with those of older and more bloody wars does not depend mainly upon the alteration of the bullet used. That, as we have seen, can do fearful things to a dense obstacle, and add to its power for mischief by the laceration caused by bony fragments which it scatters in impact. To some extent, the smallness of the canal made by it helps toward recovery. But, above all, the results are due to the treatment of the wounds by the surgeon, and the operation of those great principles which have developed under the splendid genius of Lord Lister. He has made possible the unquestionable triumph of conservative treatment. Honored as he is throughout the whole world, proud as we all are to claim him as a compatriot, his most enduring memorial will be in the multitudes whom he has been the means of saving from pain and death, and in the direction which he has given to scientific surgery for all time.

Pervading all the work in modern military surgery and principles first enunciated by Lister are manifest and to rigorous asepsis and antisepsis are due the good results.

When the recoveries from wounds in this war are made up and analyzed, it will be seen what a tremendous progress has been made in protecting the injured from disaster, even in the face of all the difficulties of the battlefield. For, while in the general and stationary hospitals the precautions necessary in modern surgery can be observed, it is, after all, at the initial stage that safety from sepsis is to be secured. "The fate of the wounded rests in the hands of the one who applies the first dressing," wrote Von Nussbaum, and the truth of this assertion has been proved every day.

(To be Continued.)

BRITISH CONGRESS ON TUBERCULOSIS.

(Continued from page 199.)

State and Municipal Control of Tuberculosis.—Sir Herbert Maxwell spoke on this subject after welcoming the delegates. He spoke of the necessity of notification of tuberculosis and of the desirability of a preliminary education, especially of the lower classes, in the general fundamental ideas of the contagion in this disease. He pointed out the difficulties which legislators had to meet and emphasized the necessity of going slowly in all measures requiring legislative enactments. When the people realize that the mortality has been reduced from 38 per 1,000 in 1832 to 14 per 1,000 in 1894, and that tuberculosis still stands responsible for the greatest share in mortality than all the other infectious diseases put together, public opinion will soon array itself on the side of the sanitarian. He also touched on the subject of legislative control of buildings, holding it desirable that certain restrictions regarding the construction of dwellings, etc., should be enforced.

Mortality from Phthisis in England and Wales.—Dr. John Tatham, of the General Register Office, presented a series of statistical studies covering the past forty years. With very few exceptions, his tables showed that for all ages there had been a decrease in this time; this rate of decrease had varied widely, however, being much greater for females than for males. Apart from many aberrant conditions, the general figures showed a mortality of 2,579 to 1,521 per 1,000,000, as this decrease in males and from 2,774 to 1,141 per 1,000,000 in females.

Social Status, Food and Paternal Age.—These factors were discussed by Dr. J. von Körösy of Budapest. Among occupations, printers showed the highest mortality, showing a percentage of 60; cutlers, 50; shoemakers, 49; dyers and millers, 49; joiners, tinkers and locksmiths, 48; masons, 46; laborers, 43; tailors, 42; bakers, and journeymen, 40; drivers, 37; domestics, 36; carpenters, 34; officials, 34; butchers, 33; merchants, 28; innkeepers, 27, and lawyers, 27. Capitalists seemed most immune, 10 per cent., and physicians showed an incidence of 12 per cent. Over 40 per cent. more deaths occurred among the poor. With reference to the food of children, when brought up at home, an incidence of 5.4 per cent.; if out, 8.9 per cent.; if fed at the breast, 5.4 per cent., and if nourished artificially, 9.5 per cent. On the question of paternal age, he showed that phthisis occurs most often among children of very young mothers, while the frequency diminished with middle-aged mothers and then rose again with mothers over thirty-five years of age.

Notification of Tuberculosis.—Dr. Hermann Biggs of New York showed what had been accomplished in New York, Buffalo and Washington. New York was the first city to encourage compulsory notification; later the State of Michigan, and the cities of Buffalo and Philadelphia followed. As a consequence of such notification and the hygienic activities put in use there had been a reduction of 30 per cent. in the mortality arising from tuberculous disease.

Voluntary Notification in Manchester.—Alderman McDougall of Manchester said that early in 1899 a scheme for the voluntary notification of phthisis was submitted to the Sanitary Committee and had been accepted by them. The necessity for a municipal hospital for tuberculosis was pointed out and the methods detailed by which thorough disinfection was carried out in the places of notification.

There was much discussion on the question of compulsory notification and a resolution was passed encouraging voluntary notification.

Tuberculosis of Childhood.—Dr. Léon Petit of Paris described the establishment of dispensaries for children throughout Paris. Much good had already been accomplished by these institutions. Dr. S. A. Knopf of New York read a paper on State Aid in Tuberculosis in Children, in which he advocated its extension. Childhood was a susceptible age. Tuberculous mothers, kissing, crawling on dusty, infected floors, trailing dresses in schoolrooms and general gathering places were among the factors dwelt on as conducive to infection.

French School Colonies.—Dr. R. Bompard said that the system of fresh-air outings for school children of Paris had proven of great benefit. Private enterprise had been supplemented by municipal aid and in Bordeaux, Lyons, Marseillès, Roubaix, Lille, Agen, Toulon and Paris, the system was in active operation. In Paris alone 4,000 children had benefited. The average length of stay was three weeks; the average gain in weight four pounds, and the average increase in chest measure about one inch.

Housing and Aggregation.—Dr. H. Coates of Manchester gave the results of an investigation of the presence of infective material in dwellings occupied by consumptives. Dust was collected in houses, obtained in the course of voluntary notification, and examined by biological methods. These examinations showed the constant presence of the tubercle bacillus in rooms occupied by phthisical patients. It was present in greater amounts and was more virulent in rooms shut off from air and sunlight. He then detailed the methods adopted to disinfect thoroughly the living-rooms which had harbored consumptives.

Dr. J. Robertson of Sheffield read a paper on the same subject which dealt with the factory, dwelling-house and workship problems. It had been amply proven that the air, light and ventilation of these places were not ample. Improvements, notably in the food supply, had been of help in the tuberculosis problem, but there was much more to be accomplished. In

workshops and factories, the amount of air space was much below what it should be.

This view was vigorously upheld by Dr. A. Ransome of Bornemouth who read a paper on the subject.

Air Supply of London.—Dr. T. Glover Lyon of London defined pure air, fresh air and vitiated air as the main types. Fifty years ago the air of London was perfectly good; at the present time, pure air was unattainable for the great majority. The present regulations of air supply for individual dwellings were considered distinctly inadequate and there was no provision made for ventilation.

Control of Meat Supples.—Dr. S. F. Murphy of London spoke of the difficulties of municipal inspection of meats with reference to tuberculous infection. The discussion brought out many expressions of opinion contrary to those of Dr. Koch.

In the Section on Climatology a large number of papers were read. Most of these dwelt on special features in places of local interest, more particularly to English and Continental physicians and are not here considered. Drs. Williams, Lannelongue, Achard Gaillard, Amrein and Hichens Zammit, Stephani, Jonnart and Guetschel read interesting papers bearing on climatology and tuberculosis.

Tuberculin in Human Tuberculosis.—A discussion on this topic was opened by Dr. Heron, who said that the remedy was a very valuable one and had fallen into disrepute because of the following factors: Its use in unsuitable cases, use of too large doses, neglect of temperature rule, increased dosage, and prejudice due to severe symptoms. He believed it to be a valuable remedy in the diagnosis of the disease.

Serum Diagnosis in Tuberculosis.—Drs. S. Aloing and P. Courmont of Lyons said that the serum reaction could be obtained with moderate regularity. It seemed to them that the graver cases gave a larger number of negative reactions. From a practical point of view a positive serum reaction was a sign of great value in favor of the existence of surgical tuberculosis.

Pretuberculous Manifestations.—Drs. A. Robin, E. Papillon and S. Bernheim read papers bearing on this subject. Dr. Robin thought that a careful study of the breathing capacity and particularly of the respiratory exchange would often lead one to a knowledge of the disposition to the disease and to suggest a hygienic régime to overcome such a tendency.

Dr. Papillon said that an arthritic tendency might reveal much the same thing. Dr. Bernheim spoke of the method of modifying the body metabolism so that a tuberculous soil, deficient in acidity might be converted into one with more acid. Chlorides and phosphates are wanting in the tuberculous soil and the frank arthritic patients rarely have phthisis. The meat cure was a means of adding acid to the body. He employs phosphate of creosote.

Lymph-Gland Involvement in Meningitis and Miliary Tuberculosis.—Drs. Haushalter and Fruhinsholz of Nancy showed that in 78 necropsies of children dying from miliary tuberculosis, 95 per cent. had tuberculosis of the tracheal and bronchial glands. Of 67 cases of tuberculous meningitis, 64 had affected glands. In almost every instance the origin of the bacillary infection which ended in the miliary and meningeal forms was in caseous tracheal and bronchial glands.

Variations in Morphology.—Dr. A. Moeller of Berlin discussed some bacilli which resembled the tubercle bacillus, notably the butter and timothy organisms, and went into details concerning their growth, characters and staining reactions, which latter features were dwelt on at some length by Dr. W. Bulloch of London.

Infectivity of Milk.—Dr. Lydia Rabinowitch of Berlin said that tuberculosis in cattle was responsible for the great increase of this disease among cattle and swine and that the milk was the most important item in this contagion. Tubercle bacilli had often been found by her in milk from sound udders; the tuberculin test was the only practical test to determine the presence of latent tuberculosis.

Immunity to Tuberculosis.—Dr. T. Yabé, of the Japanese Navy, reported on three bodies isolated from the tubercle bacillus, two of which, termed by him tuberculo-myco-protein and tuberculo-bactericidin, had the property of conferring immunity. He concluded that an immunity could be conferred, but as yet the substances were too toxic and had to be modified.

Tuberculosis in Animals.—A general symposium was held on this subject. Professor Dewar, opening the discussion, said that tuberculosis of the udder was present in about 3 per cent. of cattle and that a good tuberculin under proper precautions would give 90 per cent. of successful tests.

On the subject of the milk and meat supplies Messrs. A. W. Dollar and James King said, regarding the former, that the general interest in the subject had already resulted in satisfactory regulation of the milk supply in many countries; still an extension of the Bang system in stamping out tuberculosis in cattle was advisable. Mr. King said that tuberculosis in cattle was a cause of great loss to the farmer and to the meat-trader and that the home market suffers from American competition. The home cattle are more often affected with tuberculosis, because proper attention is not given them. This is in part due to economic reasons and partly brought about by ignorance. If farmers offered healthy cattle to the butchers, it is likely that the meat traders would not be so prejudiced against the home product.

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, May 13, 1901.

The President, Robert F. Weir, M.D., in the Chair.

Gliosarcoma of the Base of the Brain.—Dr. Henry W. Berg referred to a case which came under observation at the Mount Sinai Hospital during the summer of 1900 and was recognized as one of cerebellar disease soon after admission. The patient, a man, gave the following history: H. H., a Russian, thirty-six years old; family history negative; had never had syphilis. A week before admission he began to suffer from severe frontal headache, chiefly localized over the right eye. Later he suffered from slight fever, dizziness and vomiting. He complained of great vertigo in walking, but there was no true ataxia. Patellar tendon reflex were exaggerated, especially on right side; eye muscles normal; face slightly flattened on right side, numbness on left side of face, and hyperesthesia of skin behind the left ear and over the left mastoid area. Optic neuritis was present. The patient complained of numbness on left side of face and sensation in this locality was diminished. There was slight titubation and staggering in walking, more frequently toward the left side than the right. The diagnosis at this time was a probable local lesion of the cerebellum, or base of the brain, pressing upon or involving the fibers of the left facial nerve. Upon the basis of local specific disease he was treated with iodides and mercurial inunction. Owing to the persistent vomiting, however, the amount of iodides which he could take was very much limited. On September 28th Dr. Sachs found slight lateral nystagmus and also some vertical nystagmus; both recti externi deficient; grasp of both hands, especially the left, weakened; diminution of sensibility to touch and pain on left side of face; slight ataxia in left upper extremity; slight cerebellar titubation; hearing on left side diminished. On October 5th the patient was transferred to the surgical service but died. Autopsy showed in front of the left lobe of the cerebellum, within the dura, a firm whitish tumor measuring about 4 cm. in all directions. The tumor lies on the petrous portion of the temporal bone, just over the internal auditory meatus. The pons is indented on its left side. The nerves at the base are pressed upon. Histological diagnosis, gliosarcoma. Dr. Berg said that almost all the symptoms by which the lesion was recognized and localized depended upon the interference with the functions of the left facial and auditory nerves and the characteristic symptoms of cerebellar disease.

Diagnosis.—Undoubtedly the most important symptom noted in this case, from a diagnostic standpoint, was the titubation or cerebellar ataxia. This is not an ataxia in the true sense, but rather a staggering in walking and standing which is one of the characteristic symptoms of cerebellar neoplasms, etc. The staggering of this patient was to either side and was of the variety of cerebellar ataxia which Bruns believes to be due to a lesion of tracts of fibers passing from the brain through the superior peduncles of the cerebrum to the cerebellum, and thence through the inferior peduncles to the spinal cord. For the most part these tracts pass through the processus vermiformis. Many cases are on record, however, of small tumors of the hemispheres of the cerebellum in which the vermiformis was not involved, and yet in which typical cerebellar ataxia occurred; while, on the other hand, lesions of the vermiformis have been reported in which cerebellar ataxia was absent. In the case under discussion the tumor only compressed the left hemisphere of the cerebellum and did not affect the vermiformis even indirectly. From the presence of cerebellar ataxia, therefore, we can infer only that there is cerebellar disease, without attempting, from this symptom alone, to localize the portion of the cerebellum involved. There was at no time convulsions, either of a general type or localized. This is the rule in cerebellar tumors, which in this respect present a marked contrast to tumors of the cerebrum. The hypersensitiveness of the skin behind the ear and over the mastoid was an extremely interesting symptom, and may have been due either to an irritation of the sensory fibers of the trigeminus, or, more probably, directly to the growth of the tumor. This localized hypersensitiveness, together with the deafness and temperature, led Dr. Berg to suspect at first an abscess of the cerebellum secondary to mastoid disease. The fact that the abducens was paralyzed appears to point to direct pressure on the sixth nerve, and this paralysis, therefore, like that of the facial and auditory nerves, was an aid to the localization of the tumor.

Surgical Aspects of the Case.—A paper on the surgical aspects of the case by Dr. Howard Lilienthal was read by Dr. Berg. Craniotomy was performed. After incision of the dura, about three drams of fluid were withdrawn by aspiration. Exploration with the grooved director revealed nothing, and the forefinger was cautiously inserted for nearly two inches, but without meeting abnormal resistance. A considerable piece of the cerebellum which had been forced out as a hernia was then ablated. The patient died from shock eighteen hours after the operation. Dr. Lilienthal said that, in view of what was found postmortem he had concluded that under similar circumstances (an accurate localization having been made during the progress of the case), it would be wisest to persist in the search for a palpable lesion, even though a very considerable portion of the cerebellar substance had to be sacrificed.

Implication of the Vermiform Process Necessary for the Production of Cerebellar Ataxia.—Dr. E. D. Fisher, after describing a case in which, although it was under observation for a considerable period, the diagnosis, owing to the obscurity of the symptoms, was made only about a month before death, said that his observations had led him to believe that when there is a destructive lesion of the cerebellum the staggering is away from the side of the tumor, and when there is an irritative lesion, the staggering is toward the side of the tumor. Some years ago he made a series of experiments on dogs and monkeys which seemed to demonstrate this completely. Again, he had become convinced that staggering would not occur unless the fibers of the vermiform process were affected. He agreed with Dr. Berg that the involvement of the cranial nerves fixes absolutely the side on which a cerebellar lesion is located.

Atonia as Important a Symptom as Ataxia.—Dr. M. G. Schlapp described a case at the Presbyterian Hospital, which came under observation in December last, in which the tumor involved the right lobe of the cerebellum. The patient was a little girl, nine years old, who had been blind for a month when first seen. Among the other symptoms were headache, vomiting, deafness in the right ear, staggering toward the right, atony of the right arm and leg, and general weakness of the right side. Dr. McCosh operated and the patient survived for about ten days. Dr. Berg had stated that nystagmus was caused by pressure on the corpora quadrigemina, but he thought it much more probable that it was produced by affecting fibers from Deiters nucleus. Dr. Berg did not lay any stress on atonia of the body, but he believed that it was just as important as ataxia in the diagnosis of cerebellar disease. He also took issue with Dr. Fisher as to the effects produced by destructive and irritative lesions. Luciani's experiments were not in accord with those of Dr. Fisher, and the case of Dr. Berg did not verify his observations. It is the cases in which mixed symptoms occur which give rise to so much perplexity in regard to diagnosis.

BOOK REVIEWS.

UTERINE FIBROMYOMATA; THEIR PATHOLOGY, DIAGNOSIS AND TREATMENT. With forty-nine Illustrations. By E. STANMORE BISHOP, F.R.C.S. Eng.; President of the Manchester Clinical Society; Fellow of the British Gynecological Society. P. Blakiston's Son and Co., Philadelphia.

THE study and the treatment of fibroid tumors of the uterus have been almost exclusively in the hands of the gynecologists. The epochs of progress in this specialty have been marked by milestones indicating the proper estimate to be placed on the various pathological conditions found in the female pelvis, and determining for the gynecologist, for the general surgeon and for the profession at large which of the conflicting methods of treatment is best. Uterine fibroma is one of the pathological developments that have been subjected to careful and prolonged study and experiment, and, although we have not yet determined its incipient cause, we do know its histological and clinical history and are able to speak authoritatively regarding its treatment.

It is certainly becoming, therefore, that a special treatise should be devoted exclusively to the subject, and Dr. Bishop has produced a volume quite worthy of the theme. The aim of the author has been to present a practical work, rather than an exhaustive digest. Those who expect to find here a repository of all the extraordinary and curious manifestations of the disease will be disappointed. The anatomy, development and secondary changes are fully discussed and the author's position on various subjects is strongly fortified by appropriate and convincing cases. The gravity to the patient of the existence of fibroid disease is, as evinced by secondary changes and complications, strikingly set forth in the impressive details of a few actual cases that ran their natural course, *i. e.*, were not treated.

Whether the etiology will be found to reside in a micro-organism, in inflammatory changes due to infection, or in the development of embryonic structures is the question of the future. Into all the intricacies of etiological speculation our author does not go, but he sketches in a few, broad strokes the main features that may be capable of causing these growths.

In treatment the role of medicine is judicially discussed and the weight of authority for the use of the various medicaments carefully analyzed with final judgment negativing every one. Electricity is damned with faint praise, although, strangely enough, credit is given it for the control of hemorrhage. "It is absolutely useless, and may be very harmful in cases of edematous, calcareous, fibrocystic, sarcomatous, or necrobiotic fibromyoma and in all cases where there is concomitant inflammatory disease of the appendage it should be absolutely forbidden," says the author.

He is unequivocally in favor of operative procedure as the only justifiable method of treatment. To this part of the subject he devotes three chapters, describes in detail the various procedures, both of myomectomy and hysterectomy, and is fully up to date. Curettage of the uterus to stop hemorrhage the author condemns, as the injury done by it to the adjacent tissue and the capsule may render the tumor an easy prey to septic infection and its subsequent degenerative changes. Carcinomatous degeneration of fibroids the author declares impossible. The illustrations are not quite up to modern standards, but the book as a whole is worthy a place in every medical library.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXIX. NEW YORK, SATURDAY, AUGUST 17, 1901. No. 7.

ORIGINAL ARTICLES.

FIBROMA OF THE MESENTERY.[1]

BY J. B. MURPHY, M.D.,
OF CHICAGO.

THE following history was given by the patient: Mrs. J; aged twenty-six years; family history negative; born in Russia; has lived in the United States ten years; nervous temperament; general health good; appetite good; bowels regular. Menstruation began at the age of fourteen, was regular and normal until the patient came to this country, since which time there has been quite a profuse discharge, lasting five days. She has been married three and a half years, but has not been pregnant. She had influenza three years ago. During the past two and a half years she has complained of pain in the right side, with painful and frequent urination. Four months ago she felt a tumor in the right iliac fossa, round in shape, hard, and not particularly painful on palpation. Patient states that the tumor would change its position from day to day. Sometimes it could be felt in the right iliac fossa, sometimes in the left. Careful manipulation showed that the tumor could be pushed up as high as the ensiform cartilage when it was located on the right side, and when the tumor was pushed into the right iliac fossa the pain would disappear. After eating a full meal she felt distressed and nauseated and on several occasions vomited.

From the history given, one can readily see that there is nothing definite from a diagnostic standpoint. There are a few things, however, which are of value, but which were not especially so before the operation. When the patient was examined in my office, the tumor was easily palpable in the left iliac fossa, or, better, down in the left side of the pelvis. By bimanual palpation I could lift it out of the pelvis, but could not carry it upward to any degree, as she was sensitive to pressure. She did not state to me at the time that the tumor had ever appeared on the right side, or that she was able to elevate it at any time as high as the umbilicus. After careful palpation of the tumor it was ascertained that it was round and hard; it moved independently of the uterus, and from these findings I made a diagnosis of fibroma of the left ovary. I could not displace the tumor to the right of the spine at that time, which was doubtless due to the sensitiveness and contraction of the abdominal wall. When she was under the influence of an anesthetic, the tumor could be displaced out of the pelvis and well up in the abdominal cavity as it passed over the spine to the right side. The other symptoms had no definite relation to any intestinal lesion. The symptoms were those of uterine or ovarian rather than those of intestinal disease.

The tumor was hard and almost equally divided in halves by the mesentery. It appeared to have grown within the mesentery and spread equally from both sides of the mesenteric vessels. It was ovoid and about three inches in diameter. I was unable to palpate the intestine as it passed over the tumor, but I was able to discern an irregularity on its surface in the bimanual examination. Another feature to be noticed is that the intestine, the mesentery of which was involved, came down close to it for its entire circumference. This is peculiar to growths situated in this particular region, that is, a comparatively small tumor involves the vessels supplying an enormous area of intestine.

At the operation, as soon as the abdomen was opened, the tumor was brought into the center of the field, its mesentery ligated and twenty-four inches of the ileum excised with the tumor. Only one mesenteric ligature was used, as I compressed the mesentery after my usual plan with a uterine clamp and placed the ligature in the groove produced by the clamp, the "bite" of the ligature then having nothing but vessels and peritoneum in its loop. End-to-end union was made with button No. 3 and the rent in the mesentery closed with cutgut in a fine Mayo needle. Union was produced four inches above the ileocecal valve. The situation of the tumor low down in the mesentery prevented displacement upward on the left of the spine before operation. There is another point to which I wish to call attention and that is the small hematoma extending to the end of the loop of intestine at the site of the ligature. After I had clamped the mesentery and had applied the ligature, there was bleeding from one of the vessels in the side of the vertical incision. I put in a row of sutures, including both peritoneal layers of the mesentery in order to stop the venous hemorrhage, including in the suture a vein that drains this two-inch area, with the resultant hematoma. This brings up a matter I mentioned many years ago in connection with resections of the intestine, that is, one should remove as much of the intestinal wall as he has interfered with the vessels supplying that wall, regardless of the extent of disease of the wall itself. It has been the cause of many failures of union in intestinal resection that the arteries were ligated in the mesenteric base and the intestine which they supplied was allowed to remain with the result that gangrene followed. The danger is not so great from the ligation of the arteries as it is from obstruction of the veins, as is illustrated here, for the artery was

[1] Case presented to the Chicago Medical Society.

not included in the ligature, but the vein alone. As a result of occlusion of the vein, there was immediately extensive ecchymosis into the mesentery from the blood brought by the parallel anastomotic artery. I found from my experiments upon dogs that this frequently occurred.

In connection with tumors of the mesentery I might say they are rare and the literature is meager. They are well divided into cystic and solid neoplasms.

- Mensenteric Tumors.
  - Cystic.
    - 1. Traumatic:
      - Sanguinous.
      - Serosanguinous.
      - Serous.
    - 2. Lymphatic.
      Chyleous (the latter the most common.)
    - 3. Dermoid (or congenital.)
    - 4. Parasitic (hydatid.)
    - 5. Displacement cysts from neoplasms.
    - 6. Tuberculous.
    - 7. Cystic sarcomata (Moynihan.)
      Harris and Herzog collected 57.
  - Solid.
    - Carcinomata,
    - Lipomata.
    - Sarcomata.
    - Fibromata,
    - Fibrocartilaginous,
    - Chylangiomata,
    - Adenolymphomata,
    - Malignant lymphomata,
    - Osteomata,
    - Endotheliomata.

Cystic tumors occur about twice as often as solid tumors. One hundred and twenty-three cases of the former were collected by Begouin to thirty-three of the latter. The cystic tumors of the mesentery are made up of dermoids or the congenital cysts that occur in the mesentery from embryonal remnants, always in females (Moynihan). They are made up of dilatations and occlusions of the chyle ducts. They are made up of remnants of the peritoneum; these cysts have a serous lining. It is a peculiar fact that we rarely see a cyst of the mesentery that has an epithelial lining, with the one exception, the dermoid. While these cysts may attain an enormous size and contain frequently several gallons of fluid, Lathuraz having removed one of forty pounds, they carry with it all the time a modernate dilatation of the arc of intestine over it, and at no time do they cause gangrene of the intestine. They occur at all ages from eleven weeks (Frederic Eav) to old age. They produce few symptoms usually until they cause pressure. They are practically painless, smooth, and movable, and continue in this way until they involve or encroach upon the neighboring tissues or organs, when they cause symptoms referable to the particular organ pressed upon. They may cause symptoms of ileus of the obturation variety. They occur usually in the upper portion of the small intestine, infrequently in the lower portion. In that sense they may be contrasted with the solid tumors to a certain extent, as these more frequently occur lower down. They are usually unilocular and single, except when chylous; then they may be numerous; W. H. Wenning reported as many as fifty in a single case.

The differential diagnosis between ovarian, pancreatic, renal and retroperitoneal cysts has not been frequently made before the operation or autopsy, and when the tumor is large it is practically impossible to make the differential diagnosis. The only important sign is the presence of an intestinal coil anterior to and adherent to the tumor. This we know to be deceptive from our experience with adherent intestine to other varieties of cysts in the abdominal cavity. When the abdomen is opened, sometimes the differential diagnosis can be readily made. At other times it will be found necessary to evacuate the cyst contents before its true location can be determined. Keith says that they should not be disturbed unless they produce grave symptoms.

The treatment of these may be divided as follows: (*a*) Aspiration. Begouin collected seventeen cases of puncture with aspiration with nine recurrences. Barquehaye collected sixty-two cases with forty-seven recurrences, seventy-five per cent.; there was not a single death or unpleasant sequence. As would be expected the chylous cysts were the most frequent in recurrence after aspiration. Hochenegg strongly favors this method of treatment. (*b*) Puncture with fixation of cyst-wall in abdominal incision and drainage (Spencer Wells, Lawson Tait and others). This procedure had a mortality of five per cent. in nineteen cases collected by Péan. (*c*) Primary enucleation of cyst. This is an extremely dangerous procedure. Begouin found a mortality of sixty per cent., shock, peritonitis, and intestinal gangrene being the principal causes of death. Péan found seven deaths in eighteen cases operated by extirpation, a mortality of thirty-seven per cent. We can therefore conclude that primary extirpation should be resorted to only when the cyst is small and a small portion of the base of the mesentery involved. The interference with the mesenteric

Fig. 1.

circulation even for an inch or an inch and a half at its base may jeopardize the vitality of an enormous portion of the intestinal tract, as we know that the entire mesentery at its attachment to the spine is variously estimated at from four and a half to eight inches, carrying at its periphery twenty-two to twenty-seven and a half feet of intestine. (*d*) Primary drainage with secondary enucleation. This can be accomplished in the class of cysts in which ablation of the cyst-wall is necessary, because, owing to its histological structure, it cannot be expected to heal by simple drainage (dermoids, ecchinococcus and chylous cysts). These, however, can be enucleated with little danger when they are greatly reduced in size by drainage.

The solid tumors are of many varieties from a histological or pathological standpoint. They represent about thirty per cent. of all the mesenteric tumors. Histologically they consist of (*a*)

Fig. 2.

epithelial and endothelial growths (carcinomata and endotheliomata); (*b*) connective-tissue growths (sarcomata, fibromata, lipomata); (*c*) lymphoid growths (lymphomata); (*d*) vascular growths (angiomata and lymphangiomata); (*e*) nerve-tissue growths (neuromata); (*f*) chylangoma.

The latter are essentially retention-cysts and do not properly belong with solid tumors. The above tumors undergo numerous changes, such as chondrification, ossification, caseation, etc. They vary greatly in size and situation. They occur most frequently in the lower portion of the small intestine and may attain an enormous size. Terillon removed a lipoma weighing fifty-nine pounds, Van der Veer one weighing fifty-six pounds, Péan, fifty pounds, Shepherd, a myxofibroma weighing thirteen pounds, and Brookhouse a fibroma weighing thirteen and a half pounds.

The importance of a tumor in the individual case depends upon its histology and its anatomical relations to the vessels of the mesentery, as well as upon its size. The lipomata, the largest of the solid tumors, are often encapsulated and can be shelled out of the capsule without materially interfering with the blood supply of the intestine.

Of the solid tumors occurring in the mesentery, the most common is carcinoma, secondary to carcinoma in some other position. Next in frequency is the fatty tumor; next the sarcoma, and, after it, the fibroma, to which class the tumor in the case reported belongs.

In reviewing the histories of these cases I was unable to find in the literature more than eleven cases of fibroma of the mesentery. Those are recorded all the way from 1824 down to the present time, as shown by the following table:

FIBROMATA.

Brichiteau.	1824	Paris.	Fibrocartilaginous.	
Duhamel.	1863	Paris.	Fibrous.	
Cooper-Foster.	1867	London.	Fibrous lipoma.	
Dickinson.	1870	London.	Fibrous.	
Ladmiral.	1874	Paris.	Fibrous	
Koenig.	1890	Berlin.	Fibrous.	
Brookhouse.	1890	Nuttingham.	Fibrous.	
Belkowsky.	1893		Fibrous.	
Shepherd, F. J.	1897	Montreal.		13.5 pounds, 8 feet intestine, recovery.
Vinc.	1899	Mitrovitza.	Fibroma.	
Lexar.	1900	Berlin.	Fibrous.	
Murphy.	1901	Chicago.	Fibroma.	

Of the solid tumors of the mesentery the one most frequently diagnosticated was sarcoma. Something like a year and a half ago I saw a case of this type in consultation with Drs. Bodoin and Cartledge of Louisville. The patient was a very prominent man of that city, who had a tumor growing at the beginning of the mesentery just below the left costal arch. The tumor gradually increased in size, and what led to the diagnosis of sarcoma of the mesentery was the fact that the soft intestinal coil could be palpated over the apex of the tumor, and, as the tumor was fixed, it led to the statement that it was irremovable. The patient, however, insisted upon the performance of an exploratory operation, which was made. The small specimen removed was examined with the microscope and demonstrated to be a lymphosarcoma of the mesentery.

Professor W. A. Evans gives the following report of the specimen I present to-day: "Sections demonstrate that this is a fibroma. The fibers are mostly wavy, long and parallel in arrangement. In other zones the fibers are loosely arranged and the interfibrillar spaces have been filled with some soluble material. The blood-vessels are not very heavy walled. The cells are either long, narrow and deeply staining, or round and vesicular as shown by staining. There are no myxoma cells."

Fibromata do not appear so near the base of the mesentery as the sarcomata. The fibromata appear usually close to the intestinal wall; the sarcomata lower down, even in the retroperitoneal tissue, and on this account they greatly endanger the patient's life by any operative procedure.

The gravity of operation depends largely upon the extent of the intestinal tract that is necessary to be removed. Dr. Francis J. Shepherd removed a tumor situated deep down in the mesentery which on account of its size also formed a close attachment to the intestine and required the removal of eight feet of the intestine in its extirpation. The patient made a good recovery, even after such an extensive intestinal resection, which I believe is one of the largest on record from which a patient has recovered.

The danger of the operation consists, first, in shock and second, hemorrhage from the mesentery in separating a tumor with close attachment to the intestine.

According to the statistics given by Drs. Harris and Herzog in their joint paper, they show that forty per cent. of the cases die as a terminal result of mesenteric tumors. They do not mention the differentiation between those cases that die from the disease after the operation and those that die from the disease without operation, but simply that forty per cent. die. In looking over the literature of operations more recently collected, I find that of twenty-nine cases operated, fifteen died and fourteen recovered. There is an enormous mortality from the operation in removing these tumors, and this brings up the question, Can we in any way avoid their removal when they are either cystic or solid? Of the solid tumors of the mesentery, particularly if they are sarcomatous, there is no way of avoiding operation. As regards fibromata, in the literature it is mentioned that the blood-vessels as a rule pass directly through the tumor, and this was the condition in the case I present. Therefore there is no means of saving the arch of intestine which receives its blood-supply from these vessels.

Of the malignant neoplasms, some are encapsulated and may be removed with the capsule without materially jeopardizing the intestine. But the majority of these cases, particularly the carcinomata and sarcomata, require the removal of the mesentery for a considerable distance beyond the tumor line and necessitate extensive intestinal resection. Even then the period of immunity must be expected to be short. Many times they are so extensive that extirpation is not possible, as in the case of Drs. Bodoin and Cartledge of Louisville. In this case the diagnosis was made before the exploratory operation and verified by the physical and microscopical findings. The mortality from operation is about the same as that for primary extirpation of large cysts.

The situation is entirely different when we come to consider operations for encapsulated fatty tumors and large cysts of the mesentery. These comprise two-thirds of the tumors of the mesentery, and operative procedures for their removal are entirely different from those for solid tumors. In cysts the methods of operation have been aspiration, drainage and fixation of the cyst to the abdominal incision, primary enucleation, and secondary enucleation. The best results have been from aspiration. Statistics show that twenty-eight per cent. of the cases of cysts of the mesentery recover by simple aspiration. They further show that where the cysts have been tapped and fixed in the abdominal wound, there has been a mortality of 5 per cent., while in those cases in which the tumor has been directly removed, the mortality has reached 52 per cent. (Begouin).

There is a certain class of cases, however, that will not respond to the aspiration treatment and those are the cysts that are lined with epithelium, the dermoids. The dermoid may be fixed in the abdominal wound and drained, just as endothelial-lined cysts may be drained until contraction of the cyst-wall takes place, and then enucleated. This is the method which is particularly to be recommended in the removal of cysts in this area.

This patient was operated ten days ago. She was given liquid diet from the first and has not had an unpleasant symptom. This morning I palpated the button in the rectum through the vagina. (It was passed on the twelfth day.)

ARSENIC AND ITS COMPOUNDS; WITH SPECIAL REFERENCE TO SODA CACODYLATE.

BY CHARLES WILLIAM HEITZMAN, M.D.,
OF DENVER, COLO.;
LECTURER ON HYGIENE IN THE DENVER COLLEGE OF MEDICINE.

ARSENIC in small doses acts upon the respiration and circulation as a stimulant, but in large doses it is depressant. Whether its action as a hematic tonic is direct or not is an open question, but the fact that it increases the number of red blood-corpuscles is unquestionable.

The most marked effects of arsenic are produced upon the skin and nervous system. Experiments have demonstrated that in poisonous doses it will cause exfoliation of the epidermis. The deeper layers of the epithelium, the columnar layer, become softened, vacuolated, and separated from the connective tissue below. Sometimes the corneous is separated from the Malpighian stratum also. Dr. H. G. Piffard relates a case in which extensive exfoliation of the skin resulted in a patient who by mistake had taken a teaspoonful of Fowler's solution. Extensive desquamations have followed in cases in which it has been taken with suicidal intent. The writer remembers an instance in which a teaspoonful of the acid was fed to a pig with "homicidal intent" but the only noticeable effect on the animal was a complete exfoliation of the derma and hair. Arsenic acts directly on the epithelial cells, which become shrunken, both in cell substance and in nucleus. Brownish and grayish discolorations have been noted as effects of the long-continued administration of arsenic. Various eruptions, such as furuncles, papules and

vesicles, sometimes occur. Herpes zoster is sometimes seen in patients taking arsenic. This is probably due to a neuritis.

Almost constant effects of the internal administration of arsenic are a silvery appearance of the tongue, a slight reddening and irritation of the conjunctivæ, and puffiness of the eyelids. Large doses, or the long-continued use of small ones, may produce symptoms resembling those of poliomyelitis or multiple neuritis.

Arsenic is perhaps the most extensively used internal remedy in the treatment of skin diseases, and is probably the most valuable, provided the cases for which it is prescribed are selected. There can be no doubt of the great value of arsenic in psoriasis, its undoubted action in modifying epithelial tissue suggests its use. In eczema, not of the acute moist forms, it often acts with almost specific power. It is the only trustworthy remedy at our command in pemphigus. The papular eruptions termed lichen planus and acne yield to arsenic. It is of value in lupus erythematosus and in certain malignant diseases of the skin, epithelioma and sarcoma, etc.

In the various neuroses, chorea, neurasthenia, it is the best medicinal agent indicated. Certain cardiac and gastric neuroses are favorably influenced by arsenic. Diabetes is often cured by its use. Albuminuria dependent upon certain conditions yields readily to it. In the early stages of pulmonary tuberculosis arsenic has a *curative* action. The general nutrition is improved, the congestion and secretions of the bronchial mucous membrane are lessened, the cough is allayed, and the dyspnea relieved. Thus is the tuberculous process arrested and the patient cured.

That the use of arsenic does not always give the looked-for results along the line of diseases mentioned is not due to its inefficiency, but rather to not using it in sufficiently large doses, or in not continuing its exhibition long enough. Both of these conditions arise either from fear of its toxic effects or the actual production of them, and the remedy is discontinued. Very recently, however, the attention of the medical profession has been directed to the use of compounds of arsenic, notably sodium cacodylate. This preparation was first developed by Bunsen, but was not employed in medicine until about five years ago when Drs. Danlos and Gauthier began its use. Indications for its use are increasing daily, as it exercises a beneficial stimulating and tonic effect on all patients to whom it has been given. An almost immediate improvement in the general condition and appetite with an increase in weight is noticeable. It is eminently adapted to cases requiring large doses of arsenic and it is absolutely safe even in massive doses, being non-toxic in comparison with other arsenical compounds.

It may be exhibited hypodermically, in doses of from one to one and one-half grains daily, and up to six grains daily by the mouth or rectum. No matter in which way it is given the profound "garlicky" odor becomes discernible in the patient's breath in from three to seven days.

I herewith append brief histories of some of the cases in which it has been of decided benefit.

Case I.—S. F., female, married. History of case dates back to puberty from which time she has been exceedingly nervous. This has increased in later years. She has not been free from pain for the last two years. Complains of head pressure, headaches, backache, ovarian pains. Muscular and joint pains follow each other in succession or are all present at some time. Does not feel ill, but tires easily. Is constipated, and has periods of distressing indigestion; is anemic and has cold hands and feet. Is losing weight. On October 1, 1900, weighed 104 pounds.

Treatment consisted of the usual diet prescribed for these cases and sodium cocodylate, gr. ⅙ three times a day, before meals for ten days; then omitting remedy for same length of time. Increased dose to gr. ⅓ and gave as before. On December 5, 1900, the patient feels much better and weighs 112 pounds. Pains occur only at intervals and are of a different nature, lacking their former severity, etc. April, 1901, she is apparently well. No pains; circulation good; cheeks rosy; weight, 120 pounds.

Case II.—L. G. T., male; appearance good, physical examination negative. Complains of headache, sleeplessness and inability to concentrate mind on business. Treatment, cacodylate pill, gr. ⅖, three times a day. Subjective symptoms disappeared after the first ten days of treatment and have not returned.

Case III.—E. M. A., female, aged twenty-three years, came to Colorado seven years ago for lung trouble. Improved materially at first, but lately has "run down," lost weight, etc. Has had four attacks of "congestion or pneumonia" within the past year. Anorexia. Coughs a great deal, especially at night. Subnormal temperature in the morning, rising to 100.5° F. in the afternoon; pulse 90 to 100; dulness over right apex; upper portion of left lung consolidated.

Treatment consisted in the administration of sodium cacodylate in ½-grain doses, hypodermically, once a day for five days; an intermission of five days, and repeated in 1-grain dose for the same length of time. After the usual intermission the agent was given *per orem* in ⅖-grain doses three times a day. Result cessation of cough, appetite voracious, increasing in weight.

Case IV.—H. D. J., male, aged fifty years. Ten years ago came to Colorado for lung trouble. Had several slight hemorrhages. "Lung is now all right, but stomach is all wrong." Cannot digest anything. Gas accumulation in stomach immediately after ingestion of any sort of food and sense of discomfort is intensified, unbearably so, if anything like eating a square meal is attempted. Subnormal temperature; pulse irregular, 55 to 60; anemic; marked area of dulness over right apex; stomach dilated.

Treatment consisted in diet, milk, seltzer, zoolak; lavage; soda cacodylate, gr. ⅙, before meals. Improvement was marked from the start and still continues.

Case V.—R. E. G., male, aged thirty years. Second visit to Colorado for lung trouble. Has been here this time one and one-half years. Improved wonderfully for the first seven weeks. Had hemorrhage during October, 1899, that lasted off and on for twelve days. Temperature 103° F. During May and September, 1900, had "more hemorrhages." Very nervous; cannot sleep. Physical examination January 31, 1901, shows a temperature of 99° F., pulse 90, congestion of vocal cords, dulness over both apices, very marked on left side, weight 117 pounds.

Sodium cacodylate, gr. ⅙, was given before meals for ten days; usual intermission, then ⅓ gr. as before. April, 1901, weight is 120 pounds; temperature normal; pulse 80. He sleeps and eats well, coughs very slightly and only in the morning on first arising. Voice sounds normal.

Case VI.—B. C. D., female, married. Has lived in Colorado eighteen years. Has had "bronchial trouble" following "la grippe." Pain under right scapula, sleeps well. Appetite good, but "bloats" after meals and is losing weight. Complains principally of eczema all over; skin itches, and peels off. Temperature is subnormal; pulse 90; lungs and liver normal; stomach dilated and very tender to pressure.

Lavage was prescribed, also sodium cacodylate, gr. ⅙ and increased as indicated in the preceding cases. The lavage gave relief at once. After thirty days the eczema disappeared and the body weight is increased.

ACUTE PERITONITIS: ITS TREATMENT UPON AN ETIOLOGICAL BASIS.[1]

BY C. D. HILL, A.B., M.D.,
OF JERSEY CITY, N. J.;
SURGEON TO ST. FRANCIS HOSPITAL.

IN our student days we learned that the peritoneum is an immense serous membrane lining the walls of the abdomen, covering and protecting the organs contained therein. We learned that it is a closed bag, and that, by commencing at any place and winding the bag around the organs in a certain way, we could cover all the organs and arrive at the starting point. So we gathered up the bag and followed its meanderings "up hill and down dale," we treked along over the veldt, we jumped from kopje to kopje, from the liver to the stomach, and then took a long trail off into the omentum; turning back upon our tracks, we groped on in the by-ways and passages and turns and reflections; we struggled on and on, anchored it down here and there, to hold an organ fast, or to suspend another, or perhaps to get our own wind and bearings; we left one side of the bag behind, and tugged away at the other, and, just as we thought we were getting out of the woods, alas! we fell into a snake-hole called "the foramen of Winslow," and got swallowed up in the lesser cavity, and were unable to pull ourselves out of the morass to follow the windings of the other side of the bag.

[1] Read before the Hudson County Medical Society.

If we could never satisfactorily unravel the puzzle of the peritoneum, in all its reflections and turns, we found out that there is plenty of it to cover all the abdominal organs and to separate one from the other. When we learned that the whole glistening surface of the peritoneum is crowded with stomata connecting with lymph-channels, that, in fact, the peritoneum forms a great lymph-space, we can imagine what a wonderful power it has for absorbing liquids, whether innocuous or poisonous. So great is this power of absorption that experiments show that the peritoneum is able to absorb in one hour more than five per cent. of the body weight.

In health the peritoneal membrane acts as a mechanical protection to the abdominal organs. Under the influence of certain irritations it develops new processes which later we call adhesions, and these act as barriers to ward off infection. To show the importance of this protective power of the peritoneum, and also the frequency of peritoneal inflammation, Byron Robinson, after 170 autopsies, says, "Scarcely ever an adult can be found without peritoneal inflammations."[2] These chronic adhesions showed where there once had been acute inflammations—they were the efforts of Nature to limit a bacterial invasion, it may have been an appendicitis, a salpingitis or a traumatism to the peritoneum. But for these barriers there would have been an extension of septic materials.

Within the past two decades, thanks to the studies of the pathologist and the boldness of the surgeon (fortified by an aseptic conscience) we no longer look upon peritonitis as a disease *per se*, but only as a symptom of some other pathological condition—in other words, it is never primary but always secondary. We now look upon peritonitis as due to a germ infection, and if we follow up the sources of entrance of the micro-organisms, without which there can be no peritonitis, we come to the true causes of inflammation of the peritoneum. It is then that we will look upon peritonitis not as a disease, but really Nature's effort to ward off disease, and, as we will learn under treatment, our efforts should be directed, not against the local irritation or peritonitis, but against the onslaught of bacteria, and we will find the peritoneum itself our best assistant. Robinson says, "Peritonitis is Nature's method of repair and prophylaxis. Peritonitis saves life, while infection kills."

Those cases of peritonitis which seemed to be primary—that is, those in which no obvious cause could be found from an *ante-* or *post-mortem* incision—may have been due to bacteria which entered through some slight abrasion of the mucous coat of the intestine, which on examination was masked by the products of inflammation; or it may have been due to an injury of the abdominal wall, however slight, yet quite sufficient under certain conditions to give entrance to micro-organisms. When we call to mind that the intestinal canal is swarming with colon bacilli

[2] N. Y. Medical Journal, Jan. 25, 1896.

and other bacteria; that the mucosa may be injured by hard masses of feces or foreign bodies; that the resisting power of the patient or his peritoneum may under some conditions become diminished, it does not require any great stretch of the imagination to follow the track of the germ from its habitat in the bowel to the point of attack on the peritoneal membrane. These are the cases which are called primary or idiopathic, when our knowledge is not complete; or when there has been a history of rheumatism, syphilis or Bright's disease, have been called rheumatic, syphilitic or nephritic; but such can only very remotely be called predisposing causes.

Some of the avenues for the entrance of bacteria to the peritoneum are the following: (1) Any injury or disease of the alimentary canal sufficiently intense to cause a perforation, notably appendicitis, and less frequently ulcers; (2) any obstruction, such as invagination, intussusception, or strangulated hernia, which causes a necrosis of the gut; (3) septic conditions of the abdominal or pelvic organs, such as abscess of the liver or kidneys, and especially disease of the Fallopian tubes, giving rise to pelvic peritonitis; septic conditions of the postpartum uterus, giving rise to puerperal peritonitis, this latter often being classified under a distinct heading; (4) traumatism from within or without the lumen of the bowel, or traumatism to the abdominal wall, such as penetrating injuries caused by gunshot or stab wounds, or traumatism caused by operations.

Without going into the clinical pictures of peritonitis from its various causes, or even the variable clinical picture from any one cause, it is well to remember that peritonitis, as we term a certain group of symptoms, sometimes very distinct and again anything but distinctive, does show a wide range in its manifestations, subjectively and objectively. Sometimes the primary disease so gradually merges its symptoms into the secondary disease that it is hard to tell when the peritoneum has become infected. Again, especially if we do not know the history of the case, the peritonitis completely masks the underlying disease. The symptoms to a certain extent depend upon the degree of infection of the peritoneum which gives rise to Senn's pathological division in his classification. He distinguishes four varieties, (*a*) diffuse septic, (*b*) suppurative, (*c*) serous, and (*d*) fibrino-plastic.[3] We can by no means make out beforehand these distinctions. They really represent different degrees of infection, or, to put it in another way, they represent different degrees of resisting power of the peritoneal membrane. It is for the reason that it is impossible to tell beforehand the condition of the peritoneum, or, to speak in proper terms, the amount of septic invasion of the abdominal cavity, that some surgeons operate in all cases of appendicitis, the commonest source of infection of the peritoneum.

In operations for appendicitis we will find in one case a localized peritonitis, in another case, localized suppuration, and in a third, a general septic peritonitis; and what we do find will often not correspond with what we expected to find. Take a case of pelvic peritonitis. What a variable picture it presents! Some cases with distinct symptoms of marked sepsis readily clear up, and *vice versa;* others, beginning mildly, are followed by sequelæ entailing various chronic conditions which cause a patient to be bed-ridden for weeks and months.

There are many factors bearing on the question of invasion of the peritoneum by bacteria. The peritoneum may be more or less resistant; the particular germ invading the peritoneum may be more or less virulent; the absorption of the bacteria and their products may be rapid or slow; and the quantity of the poison introduced may be little or much.

Abbe says, "Experimental research shows that when a small amount of infectious culture of intestinal bacteria is injected it can be disposed of without fatal effect. A small quantity produces diarrhea, more a local peritonitis, still more a fatal fibropurulent peritonitis, and a larger dose. acute fatal sepsis without peritonitis."[4]

Again, bearing on this question is the individual resistance of the peritoneum. We can all look back and call to mind at least one case of laparotomy in which we could not find any break in the chain of asepsis and expected a speedy recovery, and yet about the third day we saw looming up a direful case of fatal peritonitis. On the contrary, we can remember cases in which we found such conditions as would lead us to expect an infection of the peritoneum, and yet everything went along serenely.

I would turn quickly from this aspect of the subject, as it might influence some one to trust to fate, instead of to asepsis; although it takes the burden off of our shoulders to some extent, to hear what as great laparotomist as Kelly says: "The more we learn of infectious processes, the more are we convinced that the vital resistance of the patient plays an important, if not the greater part in the resistance to infection."[5]

The place or particular part of the peritoneum where the infection occurs often determines the degree of peritonitis or sepsis. If the bacteria enter through the small intestine, so quickly are they disseminated by the free movements of the bowels that there is apt to be a disseminated peritonitis; if the infection is from the iliac fossæ or in the pelvic cavity, there usually develops a circumscribed or suppurative peritonitis. If the infection is due to the colon bacillus, the usual germ found after infections from the alimentary canal, there may be a very virulent or a mild sepsis. Staphylococcus infection is, as a rule, not very virulent, while an infection by the streptococcus is apt to be disastrous.

Treatment.—As peritonitis is a secondary disease, it is self-evident that the primary disease should be treated. If we look upon peritonitis as

[3] MEDICAL NEWS, May 8, 1897.

[4] MEDICAL NEWS, May 29, 1897.

[5] Kelly, Operative Gynecology.

an indication of absorption of micro-organisms and their products, irrespective of the source of their entrance, the treatment necessarily resolves itself into the prophylaxis of sepsis and the elimination of septic products when once introduced. It is to this general aspect of the question of peritoneal sepsis that the remainder of this paper will be limited.

To prevent the entrance of bacteria to the peritoneal cavity when a traumatism is caused, as in abdominal operations, it is essential that surgical cleanliness be maintained. We avoid depressing the vital powers of the patient by dispatch in our work, by the use of heart stimulants, such as strychnine, and general stimulants, such as injections of hot normal saline solutions. We prevent the resisting power of the peritoneum from being lessened by refraining from unnecessary handling and exposure of the peritoneal membrane. Although surgeons do not look upon the peritoneum with such reverence and fear as in pre-aseptic days, still, it should be handled firmly but gently, confidently but not recklessly, as we may need its help to do picket duty against an unexpected assault by some lurking germ.

After operations, if we find conditions that would cause us to be anxious as to subsequent infection of the peritoneum, or if we see signs of infection already beginning, we make use of the intestines to eliminate the poison. It is upon this principle that the newer and best method of treatment, that by catharsis, depends. Hence we use saline cathartics, or, if the stomach is irritable, calomel in small doses. McCosh, for this purpose, injects into the lumen of the bowel at the time of the operation a saturated solution of Epsom salts. In the course of those diseases which furnish avenues for the entrance of bacteria to the peritoneum, the same principle applies as to the use of cathartics. In the treatment of the primary disease before peritoneal sepsis has commenced, or after it has already set in, the question, Shall we give opium to relieve the pain, or shall we give cathartics to relieve the sepsis, will often arise.

Since the causes of peritonitis are better known and the conditions met with better understood—that the danger is not from the amount of the peritonitis, but from the amount of sepsis—the opium treatment has been superseded by the more rational treatment, that by catharsis. Cathartics should be used instead of opium, because we thus eliminate the poison and prevent or lessen tympanites, which may be the most distressing symptom to the patient. Opium was used with the idea of checking peristalsis to lessen the peritoneal irritation, but we know that it locks up the poison as well as the bowels, and increases the tympanites. But there are cases where it requires the courage of one's convictions and, as the laity would say, "hardheartedness," to carry out this line of treatment to its logical conclusion. Suppose one is called to a case of beginning peritonitis from some tubal trouble, the commonest source of peritoneal infection in females. Before any grave constitutional symptoms arise, there may be the most agonizing pain, and it would require an adamantine heart to resist the giving of quick relief afforded by morphine. Yet we believe that much of the long and tedious ensuing sickness and suffering might be avoided by stuffing our ears, as did old Ulysses, and by giving a brisk saline cathartic, instead of listening to the Siren's cries for opium. For the relief of the pain we may get some help from external applications of ice, and internally we may cautiously use some of the coal-tar derivatives. Until the cathartic accomplishes its purpose we might, in some cases, be justified in using hypnotic power.

To get the beneficial effects of cathartics the treatment should be instituted in the very beginning, before the peritoneum has become thoroughly septic. We cannot carry out this line of treatment in perforations of the intestines, as we would be adding fuel to the flames. Here the only treatment of any avail would be to operate and repair the perforation.

Before the operative treatment is taken up, a few words as to general treatment may be said. As a peritoneal infection is very depressing to the patient—we may say, a veritable "solar plexus blow"—we should combat the weakness and keep up his strength by alcohol and the usual stimulants. The tympanites is best relieved by the use of the rectal tube, and I have time and again seen the aspect of a case change for the better after the escape of gas through the tube. One of the most striking cases that now recurs to me was that of a boy operated on for suppurative appendicitis. About the third day tympanites was so marked and the depression so great that it seemed the patient would quickly succumb to sepsis. The tube was passed high up and gas freely escaped, then a copious fecal discharge passed, after a high enema, and the patient immediately got better.

In cases in which the septic products have not been eliminated, but the peritoneal barriers have been sufficient to limit or wall off the septic process—that is in localized abscesses of the peritoneal cavity—a type we see in some cases of suppurative appendicitis, or in collections of pus in the pelvic peritoneum, the indications for treatment are to open and drain. In some of these cases, for fear of breaking up adhesions, we are apt to do too little and leave other foci of infection. This question was so thoroughly and ably discussed by Dr. Gray at our last meeting that I will take up that formidable type of peritoneal infection, called general or disseminated peritonitis, in which the barriers of Nature are swept away by the septic flood.

We may see this type after a perforation of the alimentary canal in which a large quantity of septic material is quickly introduced within the peritoneal cavity, or by rupture of an abscess wall, or, occasionally, after operations, or by extension from a septic uterus. If, occurring after an operation, the patient is so overwhelmed by the poison that we may try to ease our conscience by attributing the death to shock, and we may try to

prove it *postmortem*, as we find but little irritation to the peritoneum. In some cases disseminated peritonitis develops so quickly that the primary disease is completely masked and the patient is often beyond the reach of help by any treatment. We might here use opium as a means of ewthanasia. I saw a case of this quickly fatal type about two months ago. The patient while convalescent from influenza was taken suddenly with cramps. The attending physician, thinking it an attack of acute indigestion, did not feel apprehensive. The next day through stress of work he did not see his patient till five o'clock in the afternoon—about thirty hours after the attack of cramps—when to his amazement he found him in collapse. I saw him at this time and we decided that the alarming peritonitis was probably due to a fulminating case of appendicitis, and that if he responded to stimulants we would operate. But in spite of our efforts he steadily sank and died before morning.

Up to within a few years ago cases of disseminated peritonitis were looked upon as inevitably fatal, but recognizing that if we can open the abdomen in the early stage of the disease and cleanse the peritoneum of the septic products, some cases may be saved, surgeons now feel justified in making this effort, and giving the patient some chance of life. While we may not be able to cleanse every nook and corner of the infected area, we can certainly remove some of the poisonous products, and this is infinitely better than to allow the peritoneal cavity to be literally deluged by the poison.

To get the beneficial effects of this treatment, as we would naturally expect the statistics to show, it should be carried out as early as possible and before the vital powers of the patient are too much depressed. The whole area infected should be cleansed, and gauze drains placed in the iliac fossæ, between the coils of intestines in the pelvic cavity, in the region of the liver and in places where infectious material is concentrated. If there are only small purulent foci these should be sponged off with pieces of gauze wrung out of salt solution; if there are larger collections more can be accomplished by copious irrigations of hot salt solution.

Serum therapy has aided in the cure of this type of peritonitis, and much more may be hoped for when the proper serum can be found and used for the particular case in hand, that is, for each bacterial invasion the corresponding serum can be used.

I can see at no distant day a picture which I will label "Hope Astride Science." In this picture I see a patient on the operating-table, and, although his peritoneum has been invaded by hordes of bacteria, still he has a hopeful expression on his face, so confident is he in the science and skill of the medical men around him. There are five of these men of science, all arrayed in spotless gowns, all working in harmony and with clock-like precision. First is the electro-therapeutist, who turns on the X-rays and marks out the infected area; second, is the spinal anesthetist, who dulls the patient's pain, but not his senses; the third is the family physician, who still looks out for the general welfare of his patient; the fourth is the surgeon, who opens the abdomen, and, while he performs the peritoneal toilet and places the drains, the last man of science, the pathologist, takes his specimen of poison, places it under the microscope, names the germ and applies the proper antitoxin.

Take another picture, drawn from the past; it is called "Despair Lashed to Conservatism." In this picture I see great crowds of young men and women and children and the aged, of all colors, nationalities, and walks of life, but all with the same Hippocratic expression suffused over the whole face except the eyes, which have that ecstatic look given by the poppy; each presses one hand over the right iliac region, and in the other holds aloft a scroll, and on every scroll I see this couplet, printed in red letters:

Peritonitis! the Doctors cried;
Opium, the Doctors plied.

102 Grand Street.

A PLEA FOR THE BETTER APPRECIATION OF THE LIMITATIONS OF OPERATIVE WORK.[1]

BY A. M. CARTLEDGE, M.D.,
OF LOUISVILLE, KY.

AT the outset permit me to say that I fully recognize the risk to criticism one incurs in attempting to define rules for the guidance of the many in a question of such magnitude as the title of this paper embraces. Every surgeon must be his own arbiter in deciding such questions, and the judgment he displays will depend upon his professional learning and wisdom. Yet we are at times led to believe that some otherwise brilliant surgeons are masters in nearly everything connected with our science and art except this very important point. There are many reasons for this. Our advance has been so rapid and the conquest of disputed fields so dazzling that it is natural in some instances that an unwarranted enthusiasm should be developed. Again, short-cut roads to diagnosis are responsible for many unjustifiable surgical operations.

The methods of surgical diagnosis have undergone striking modifications within the past decade and have curiously influenced operative work. The older surgeon made his diagnosis of abdominal and pelvic lesion slowly, the accuracy of such diagnosis depending largely upon his skill, which skill at that time consisted of a delicate sense of touch, trained eye to detect asymmetry, keen ears to differentiate sounds elicited by percussion, and methodical investigation of all symptoms both subjective and objective. The result was, his diagnosis having been made, he next carefully and with abundant time before him considered the advisability of operative intervention. It is true he often found, after exploration, his

[1] Presidential address delivered before the Southern Surgical and Gynecological Association, Atlanta. Ga.

most cherished diagnosis a fancy, but, where the conditions did coincide with his carefully-arrived-at conclusions, he was in position to bring the best judgment to bear in his operative methods. Later, when evolution in surgical diagnosis reached the stage where greater accuracy was demanded, the exploratory incision for diagnostic purposes was inaugurated. The result was that the finer arts, which constituted the personal skill of the older surgeon in diagnosis, from disuse have fallen into atrophy and, I am sorry to say, with some men seem to be lost or, more correctly stated, never have been gained.

Diagnoses made thus rapidly and more accurately had one drawback in that the revelation was so sudden as to place the surgeon in the position where he must decide the question of operative limitation quickly and without the judgment which sometimes comes of more deliberate thought. That this necessity for quick decision has developed rapid mental deduction from a given abdominal condition is attested by the brilliant work of abdominal surgeons in every part of the world to-day; that it also leads to transgression of surgical limitations or possibilities is one of the purposes of this paper to show. Asepsis, by removing the greatest danger in operations, has led to some unwarranted operations which have been little short of unreasonable experiments.

It is as much a part of the knowledge of surgery to know its limitations, or what it cannot do, as to be justly proud and ready to perform that which it has every good reason to believe will be productive of relief and cure to the thousands of unfortunates who seek its aid. From every standpoint there is much to be gained by a better appreciation of our operative limitations. It is a poor balm to our wounded pride and poor solace to the departed one's friends for us to say, "Well, he (or she) would have died anyway from the disease in a short time." We should remember that, while ours is not an exact science, it is daily becoming nearer one and the people, or what we are pleased to call the laity, setting the standard by our brilliant achievements of recent years, practically consider it so now. If we cannot do good, let us avoid doing harm; this is a good rule to guide us in performing surgical operations.

It is not to be inferred that carefully planned work coming under the usual head of experimentation should never be undertaken, for without such originality and boldness in the past, we would not enjoy the wonderful achievements of our science to-day. We would plead for more careful diagnosis with an especial view to the detection of attending visceral disease; in short, to try and become more expert prognosticians.

There are two phases of surgical practice alone, the careful observance of which would reduce the mortality of surgical operations so low as to cause us to believe that exactness had almost been reached. I refer, first, to greater care in the detection of kidney lesions and the institution of measures to correct this frequent cause of unfortunate operative termination, and, second, the still prevalent practice of operating upon hopeless cancer cases. We cannot honestly place the disastrous terminations from these in the category of accidental, unforeseen and unavoidable happenings. I venture the assertion that there is not in this audience a surgeon who, if he reviews his mortality for the past two years, but will find that fifty per cent. of such mortality was from causes that he should have averted, either by displaying the excellent judgment not to have operated upon inoperable cases, or by dereliction in not preparing against a weak point prior to operation. We all detest a surgeon who will operate only on selected cases, avoiding risk to save his reputation—he does not deserve the name of surgeon—but we can go too far in the other direction and in our enthusiasm to relieve humanity give too many so-called "only chances" which as often prove to be "last chances."

In reviewing the field of abdominal and pelvic surgery, it would seem that surgical limitation is most often exceeded and mortality unnecessarily increased in operations for general septic peritonitis, extensive carcinoma of the ovaries, uterus and intestines, and in operations upon the gall-passages in long-continued and profound cholemic patients without adequate preparation.

I beg your indulgence for what may seem a protest against the too-frequent practice of operating in these affections. We have every reason to believe that the advocacy of laparotomy in general septic peritonitis by those high in authority in abdominal and pelvic surgery has led to the performance of this operation by those of less experience in utterly hopeless cases of the disease. It is easier for the experienced surgeon to say at the bedside that a given case is hopeless from any line of treatment, or is a justifiable one for operation, than to describe on paper or by means of discussion, the differential points which should determine action. Every man's experience will ever remain his most impressive guide, and certainly those with little experience in operations for general septic peritonitis must either be impressed with the teachings of those in authority and who have had experience, or their early work will be fraught with a high mortality in this class of cases. I am not prepared to say that cases of general diffused septic peritonitis have not been saved by laparotomy, irrigation and drainage; certainly the reports of such cases have appeared in our literature from time to time; but I am prepared to say that up to the present, the mortality of such operations in exaggerated types of the disease is so great as to make it an unwarranted procedure, I am strongly impressed with the belief that the successful cases reported have been cases of beginning general peritonitis, or of widely extending yet circumscribed peritonitis. We all know the difficulties that sometimes attend the recognition of the extent of the lesion. Given a case where a focus of virulent infection has suddenly emptied its contents into

the peritoneal sac at some point, be it the appendix, a septic tube, or intestinal lesion, if the sepsis has rapidly augmented, spreading to the entire peritoneal covering, characterized by no adhesion of limitation, manifesting itself objectiveiy by a pulse-rate of 140 to 160, great abdominal distention, paresis of the intestine from toxemia and gas which precludes the possibility of attaining results from purgation, and the destruction of abdominal breathing, I do not believe that any surgical operation which has for its purpose the administration of an anesthetic, opening the peritoneal cavity with its subsequent drainage, can be other than productive of the greatest harm and hasten the usual disastrous termination.

In reply to the argument which may be made that if two such cases out of a hundred can be saved by this procedure, it would still be justifiable, I would say that a painstaking observation of a great number of these patients has led me to believe that probably five per cent. would be saved by Nature aided by such measures as sustaining the patient's heart, the free use of saline infusions, etc. Of course we recognize that the question will ever arise as to the accuracy of the diagnosis. And here, again, I must say that we have our experience at the bedside to assist us in this decision; but of one thing we feel sure, and that is that we have all in the past operated upon many of these cases that were hopeless, that we have thus swelled our mortality list and, to that extent, have brought surgery into disrepute.

Much might be said by way of elaboration in differentiating the operable and inoperable cases of septic peritonitis. Certainly we are often able to save patients with a beginning diffused septic peritonitis, and it is in distinguishing how far the case has advanced, whether or not it has transgressed the operative stage, that our wisdom is asked to decide.

It seems pertinent to suggest that in general septic peritonitis we should pay especial attention in deciding for or against operation to the following points: The duration of the disease and the condition of the intestinal tone. Cases of diffused septic peritonitis of more than eighteen hours' duration do not promise any relief from operation. Cases of diffused septic peritonitis where careful auscultation and other tests show that the vermicular action of the bowel has been lost promise nothing from operation. I have found a most excellent working rule in these cases to be as follows: If we cannot move the bowels before operation in cases of diffused peritonitis, we will never be able to move them afterward.

It would seem opportune for us to institute a careful scrutiny of our work in the fields of uterine, ovarian and intestinal carcinoma. These, especially the former, constitute a large part of the work that we are called upon to do, and, while a paper dealing thus generally does not permit of going into the details of this particular subject, certainly we have exceeded our surgical limitations in operating upon inoperable cases of cancer, especially of the uterus. Unless we approve of removing the uterus for cancer as a palliative measure, which is of doubtful propriety, there are few cases of uterine carcinoma in which we can hold out any promise of non-recurrence to the patient by radical operation. There will probably be a time when we will see a larger percentage of co-called favorable cases. The results of operative intervention will then be more promising; but the practice in many quarters of removing carcinomatous uteri where the disease has extended widely into the pelvis, the pelvic glands, and frequently to both the bladder and rectum, can have but one effect—if we are honest in our statistics—and that is to increase our mortality unnecessarily, for there must be a mortality in these cases although it be small.

The same is true of attempts at removal of double ovarian carcinoma where the broad ligaments and frequently the peritoneum are involved. It seems that many of these patients could be spared even the minor danger of exploration if we would exercise greater care in our method of diagnosis.

Perfect scientific honesty demands that we should pursue but one general plan in deciding upon an operation for carcinoma situated anywhere in the body, and that is, if it be not possible to extirpate it entirely and radically, not to attempt radical operation at all.

Before closing these desultory remarks I wish again to impress upon the members of this Society the great importance, as a means to lessen mortality, of carefully preparing cholemic patients before subjecting them to operation. We all known that patients suffering from long-continued and profound jaundice are undesirable surgical subjects. We are not warranted in subjecting these patients, whose kidneys and often hearts have become diseased from long-continued circulation of bile in the blood, to an operation until we have instituted measures now in our possession which gradually relieve these complications and increase the chances of their recovery fully fifty per cent. I refer in this connection to the systematic use of the normal salt solution for a period varying from one to three weeks prior to operation.

Another class of patients amenable to the same course of preliminary treatment are cases of inefficient renal action. We are not justified in performing a serious surgical operation upon a patient with impaired kidney action if there is time to overcome such deficiency by the use of salt solution beforehand. The observance of this practice would probably reduce the mortality in our entire surgical work very close to one per cent.

While I have probably told you nothing new and nothing that you did not already know, if I have succeeded in impressing you with the observance of some points in practice that have seemed to me to be places which need mending and which will do most to lessen mortality, I will feel that the effort has not been in vain.

THE ETIOLOGY OF MELANCHOLIA.

BY H. H. STONER, M.D.,
OF HIGHMORE, S. D.

INASMUCH as post-mortem examination of the cortical cells of the brain taken from those who have died from melancholia has failed to throw any light whatever upon the pathological processes which underlie this form of mental alienation, any suggestion which may lead toward a solution of this problem should receive attention commensurate with the logic presented.

That the cortical cells, or, more correctly speaking, the psychical neurons, *viz.*, the pyramidal cells, the Golgi cells, the Cajal cells, the Martinotti cells, and the polymorphous cells are the agents which receive and interpret the distressing sensations cannot be denied. The question is, however, Is a diseased condition of these neurons the primary cause of the disorder, or do they in this disease functionate normally, correctly interpreting the sensations which are poured in upon them from nerves whose origin is outside the cerebrospinal axis? To assert the latter may at first thought seem as preposterous as it is bold, but a little careful scrutiny, I believe, will divest it of many of its apparent absurdities.

All must agree that the quality of a sensation is dependent upon the kind of stimulus which induces it, and that the sensation arises in consequence of the disturbance of the cortical cells of the cerebral hemispheres. The stimuli caused by the tickling of a feather and the stab of a knife on any specified point of the skin are received by the same set of psychical neurons, yet how differently are the two sensations interpreted! It must be admitted that in each instance the brain cells repond normally to the stimulus. Not because the knife-stab produces acute pain could it be said that the psychical neurons were acting disorderly. If a certain form of stimulus produces pleasure and another form produces pain, can it be asserted that the former represents a normal and the latter an abnormal activity of the cortical cells? If they act at all, they must, as far as they go, act normally. I do not mean to say that, if a single group of cells responds to a stimulus, all its related associates necessarily respond normally. What I mean is that if a group or cluster of cells responds at all to a stimulus, it can only respond in one way, the result of which gives rise to a sensation or a conscious state, and this, in itself, must necessarily be normal. The question of associated ideas is here left entirely out of account.

Now, if this be true, a patient may pass through a siege of melancholia from the moment of its inception until the time of his death without any pathological changes whatever having taken place in his psychical neurons. His mental apparatus might go on throughout the whole course of the disease correctly interpreting the sensations which overwhelm him.

From whence, then, emanate the stimuli which give rise to these painful sensations? The answer, I believe, is to be found in tissue metabolism. Melancholia is preeminently an emotional disease and the emotions arising therefrom are invariably of a painful character. Now, if it can be established that the metabolic process is answerable for the normal emotions, I believe we may have the foundation laid for the solution of the so-called abnormal emotions attendant upon melancholia. Let us, then, briefly study the cause of the emotions.

Every one is familiar with the fact that a direct relation exists between the vegetative functions and the manifestation of the emotions. Take, for instance, the drying up of the salivary secretion attendant upon a confused state of the mind; the inhibition of the lacteal function as a result of madness; the increased urinary secretion attending a state of expectancy; the sweating of perplexity, the tears of sorrow, the blush of shame, and the pallor of fear. These and many other like phenomena go to prove indubitably that the emotions and the metabolic process are intimately related. More than this, the evidence seems conclusive that the emotions are wholly dependent upon the vegetative functions.

The sympathetic nervous system presides over the organs of vegetative life. They consist of both motor and sensory neurons. They convey motor impulses to the tissues and transmit sensory stimuli back to their reflex arches and to the cerebrospinal centers. By this means the normal balance of metabolism is preserved. A surfeit of blood in an organ sets up a stimulus which, being conveyed centralward over the sensory sympathetic neurons, passes over the reflex arch which unites them with motor sympathetic neurons and back again to the tissues whence the stimuli originally arose. Such a stimulus has the effect of constricting the walls of the blood-vessels and so thereby diminishing the supply of blood to the part. On the other hand, an inadequate supply to the part produces a stimulus, but of an entirely different character; this stimulus, when reflected back to the walls of the blood-vessels, produces a dilatation of their walls and permits an extra supply of blood to be poured into the tissues. Both a constricting and dilating kind of stimulus passes over the same set of sympathetic neurons, just as a pleasing and a painful stimulus passes over the cerebrospinal neurons. It is the character of the stimulus and not the kind of neuron which produces the phenomena of dilatation or constriction of the walls of the blood-vessels. This is much more rational than the theory that the vasomotor sympathetic neurons are composed of two functionally different sets—vasoconstrictors and vasodilators, and that the former responds to only one kind of stimulus and the latter to another.

In the ordinary functioning of the sympathetic system these stimuli pass over the reflex arches and back to the tissues without falling upon the psychical apparatus, and, hence, no sensation arises in consequence therefrom. But if these sympathetic neurons be charged with a stimulus

beyond their capacity of reflecting over the reflex arches, the surplus must switch off to the cerebrospinal system and reach the psychical apparatus. Here this peculiar form of stimulus produces a sensation utterly different from that produced by stimuli carried in over the cerebrospinal system. It is of an entirely different character. The sensations incident to such an impulse we call an emotional feeling. Emotions arising primarily from the tissues are, however, pathological. The normal emotions have quite another origin. They follow as a result of intense impressions conveyed by the cerebrospinal sensory neurons to the psychical apparatus which, overflowing, pass out over the vasomotor sympathetic system to the tissues and there produce the metabolic effect, which upon being retransmitted back to the brain by the sensory sympathetic neurons is there translated as an emotional feeling. We assume that a stimulus which enhances the metabolic process gives rise to a pleasurable emotional state, while one that inhibits it produces an emotional feeling of distress.

Now, it follows with a directness that cannot be questioned that if, in tissue metamorphosis, *destructive* metabolism is not adequately balanced by *constructive* metabolism there must arise, in consequence, a stimulus identical with that produced in the normal state by an inhibited flow of blood to a part. That is, there must follow a painful emotional state. This, I infer, is the pathological condition which prevails in melancholia. Every symptom is indicative of disturbed metabolism; the slow heart, the coated tongue, the torpor of the secretory organs, insomnia, loss of motor energy, and general debility. It is noteworthy in this connection that patients suffering from melancholia have been previously enfeebled by a long-continued sickness, defective digestion, inadequate or improper food supply, bad hygienic environments or some of the forms of anemia. No matter what may constitute the primary causative factors, any condition which materially interferes with normal constructive metamorphosis is sufficient to set up the metabolic stimulus—the cry of the starving tissues for better nourishment.

But, it may be asked, if the psychical apparatus passes through unscathed, how are we to account for the terrible mental depression which is so pathognomonic of the disease, and how are we to explain the delusions which so often accompany it? The explanation of the mental depression is to be found in the fact that the patient's mind is wholly absorbed with the painful emotions which fill his bosom. If left to himself outside stimuli are incapable of finding their way into the precincts of his brain; he is so completely overwhelmed by the painful emotions emanating from the tissues of his body that his entire mentalization is concerned with this, and this alone. He can, however, be momentarily aroused from his state of misery, and it will be found that when his mind is diverted from his state of introspective wretchedness it is capable of reasoning logically and of arriving at correct conclusions. When again left to himself, however, his mind becomes completely swamped in the painful emotions which pervade it. The psychical cells are not at fault; they correctly interpret the sensations which are thrust with such awful force upon them. However, if the tide of painful stimuli be momentarily turned aside, they will be found to respond as readily to other forms of stimuli as they do to those of a painful emotional nature.

It need scarcely be remarked that the delusions of melancholia are only memory pictures which are recalled by the character of the incoming stimuli. As these latter are of a painful nature, so must the memories recalled necessarily be of the same character. The vividness of these pictures, like that of dreams, is occasioned by the fact that the mind being concentrated upon the one theme of misery, the psychical neurons not implicated in this mental process fall out of functional relation with each other, and a train of consecutive reasoning is utterly out of the question. Association of thoughts cannot be accomplished, so that when the neurons constituting a group, say in the auditory center, are by any means approximated, if the associated groups belonging to it are not also consecutively brought into functional relation so that a train of reasoning may be followed out, the impression will stand out as a bare auditory sensation, and a voice seems to whisper or shout into the ear.

The seat of the normal emotions appears to be located in the chest for the same reason that common sensory impressions are referred to the site at which the nerve is stimulated. The heart and lungs are the central bureau to which the whole economy appeals when in need of assistance; they, in consequence, stand the brunt of the whole metabolic process. The greater part of the stimuli which is translated into emotional feelings, therefore, emanate from these organs, and the sensation is, accordingly, referred to that locality. Victims of melancholia, if they are able to correctly interpret their feelings, refer the seat of their misery to the thorax. I have under my care at the present time an exceptionally intelligent lady who is suffering from this disease. She tells me that the source of all her trouble seems to be in her chest. Upon awakening in the morning, the first sensation she receives is an awful feeling of despair which seems to well up, like a specter, from her bosom.

The successful treatment of melancholia, while it is purely empirical, goes far to prove the validity of the theory here advocated. The only form of treatment which offers any hope of success is one tending to reestablish the normal balance between destructive and constructive metamorphosis—rest, tonics and good, assimilable, wholesome food are these agents and a careful study of the physiological balance sheet will point the way to the best way of accomplishing results.

MEDICAL PROGRESS.

The Fundus of the Eye in Kidney Disease.—The use of the ophthalmoscope in kidney disease is secondary in importance only to the examination of the urine, and the information obtained is frequently of far greater prognostic value than that gained in any other way. E. JACKSON (*N. Y. Med. Jour.*, July 27, 1901) says that of 419 cases reported by Belt seventy-two per cent. showing retinal changes due to nephritis were dead within one year and ninety per cent. within two years. A little practice will enable any physician to detect important changes. A brief mydriatic, such as cocaine or homatropine, one-fifth of one per cent., is usually needed. The changes are more marked around the macula or, at least, are more characteristic at that point. The veins are dilated and tortuous, other parts of the veins being frequently hidden in a swollen hazy retina. Next, hemorrhage may be found anywhere in the retina. Swelling and opacity of the retina are usually confined to patches. White spots arise from fatty degeneration and are most characteristic when arranged in rows radiating from the macula.

The Veldt and Natal Sores.—V. BISHOP HARMAN (*Lancet*, July 13, 1901) says that the Veldt sore is a vesicle forming in the stratum lucidum of the epidermis. Cultures from the serous discharge yield a most interesting diplococcus. It is distinctly thermophylic and extremely resistant, flourishing at a temperature of 110° C., dry heat, and developing luxuriantly after being soaked in a 1-1,000 bichloride solution. The sore is found only in the tablelands of South Africa. Twenty per cent. of the British troops were affected and, strangely enough, the mounted men suffered in twice the proportion to those on foot. It affected the Boers also, but not to the same extent as the British. The Natal sore differs in that it occurs only in swampy districts and affects the derma. Both in film and culture preparations it yields in every case a typical staphylococcus pyogenes aureus.

Septic Endocarditis.—H. LENHARTZ (*Münch. med. Woch.*, July 9, 1901) describes septic endocarditis as that form of valvular inflammation which is caused by specific pathogenic bacteria. The most important of these are staphylococci and streptococci, and, less frequently, pneumococci and gonococci. All cases may be roughly divided into two groups, (1) that in which the endocarditis is merely part of a general sepsis and (2) that in which its symptoms exceed in severity those of other lesions which may be present. The first group admits of a subdivision into two classes according to the vegetations forming delicate or voluminous masses. Auscultation will usually betray the latter condition, but may easily fail to reveal the former. Of 38 cases observed by the author 20 were male, 12 occurred between the twentieth and thirtieth year, and in 18 the mitral valve was affected. The disease lasted a period varying from four days to seven months. It is the more chronic cases which require special attention, since it is not generally known that septic endocarditis may run so protracted a course. In 12 of the cases, an old endocarditis was present, yet in 2 the acute process spared the chronically inflamed valve. Etiologically considered, 7 cases followed the introduction of catheters and bougie or other urethral manipulation, 5 cases developed during the puerperium, 4 after a gonorrhea, and 5 secondary to a croupous pneumonia. In 2 cases respectively an angina and a cholecystitis with pylephlebitis were looked upon as the cause. Twenty-eight cases were examined bacteriologically during life and after death with the following result: The staphylococcus was found 8 times, the pneumococcus 6 times, the streptococcus 10 times and the gonococcus once. Only one variety of germ was found in each individual case, and in the more chronic ones repeated blood-examinations disclosed the same germ, generally in increased numbers. Great stress is laid upon the value of the bacteriological examination, since by it alone can it be decided whether an endocarditis is septic or rheumatic, *i. e.*, dependent upon some germ which has as yet eluded detection, since all blood-examinations in these cases have been absolutely negative. The clinical picture of the more chronic forms in general is a uniform one; the disease rarely begins with a chill, but usually insidiously with a prodromal stage, with malaise and pain in the bones and joints. Anemia, cachectic appearance, cardiac murmurs, enlarged spleen and considerable fluctuations of temperature, with chills, develop when the malady has had a good start. The temperature is subject to considerable variation. Some patients never experience chills; in other cases they are of quotidian occurrence, and in still others they are entirely erratic in their appearance. Even with far-reaching destruction of the valves a murmur may not be apparent. The question as to whether there is a malignant rheumatic endocarditis, *i. e.*, an endocarditis with negative bacteriological findings and severe and fatal course, the author answers in the affirmative. In a general way streptococcus endocarditis gives an intermittent and staphylococcus endocarditis a more continuous temperature curve, while with pneumococcemia and gonococcemia an irregular, highly remittent and intermittent type prevails. The prognosis is serious, but not hopeless, and the problems which the treatment offers have not yet been solved despite the various sera.

A New Form of Narcosis.—B. KORFF (*Münch. med. Woch.*, July 16, 1901) has tried Schneiderlin's method in 80 cases as follows: At 7 o'clock in the morning the patient is allowed a fluid breakfast consisting of milk, tea or coffee. At 8:30 the first dose of scopolamin,

0.0004 gm., and morphine, 0.01 gm., is given. This is repeated at 10:30. If necessary, a third dose is administered at 12. One hour after the second or third dose, the operation is begun, sometimes with the aid of a few drops of chloroform. The method on the whole gives satisfaction in adults, children and the aged, and is only rarely followed by untoward symptoms.

Home Treatment of Tuberculosis.—As soon as the diagnosis of pulmonary tuberculosis is made it is now generally considered necessary that the patient should go to the mountains. In many instances this is impossible and is certainly a great hardship to a large number. I. H. HANCE (*N. Y. Med. Jour.,* Aug. 10, 1901) insists that by careful attention to the three fundamental needs of the patient, fresh air, good food and rest, many modern homes can be used successfully as places for treatment for tuberculosis. Fresh air is required every day and every night, the more the better. At least one window should be open the year around. For summer, tent life night and day is the ideal one. Minute directions must be given in regard to the regulation of fresh air. Overfeeding is the principle to act upon in all cases, whether feverish or not, whether incipient or advanced. Rest should be absolute in all febrile cases and fatigue should always be avoided. Exercise should be under the control of the physician and carefully watched. The wearing of proper clothing and hydrotherapy are very important adjuncts in the treatment. The necessity for climatic changes is thus frequently and successfully avoided.

Injections of Iodo-Mercuric Cacodylate in Syphilis.—The effects of hypodermic injections of this preparation have been studied in 31 cases of secondary and tertiary syphilis by L. BROCQ, CIVATTE and FRAISSE (*La Presse Méd.,* July 17, 1901). Treatment was commenced by daily doses of ½ grain, and when necessary the dose was doubled. The needle was thrust perpendicularly into the buttocks, giving in reality an intramuscular injection. Grave and rebellious cases were selected, most of which had resisted other forms of mercurial treatment. Satisfactory results were obtained in twenty-four cases. Important failures occurred, notably, in cases of grouped papulo-squamous syphilides. The treatment is said to be contra-indicated in the following cases: (1) Predisposition to pigmentation of the skin; (2) in tuberculous patients having a tendency to pulmonary congestion or hemoptysis; (3) where gastro-intestinal disturbance occurs. Among the advantages of iodo-mercuric cacodylate, the following are stated: (1) It may be prepared in aqueous solution, sterilizable without danger of decomposition, and miscible, without precipitation, with blood-plasma; (2) subcutaneous administration of such solution produces little or no pain and no abscess; (3) excellent results are obtained in cases of pronounced syphilitic malnutrition, emaciation and neurasthenia, in cases of rebellious mucous patches and ulcers, in the presence of seborrheic complications, and in most cases of tertiary syphilis.

Test for Lactic Acid.—The presence of lactic acid in the stomach contents is very suggestive of carcinoma when a test meal has been given. An easy and reliable method of testing for this acid is given by M. I. KNAPP (*N. Y. Med. Jour.,* Aug. 10, 1901). A weak solution (1 to 2,000) of ferric chloride and some ether are required. To one cubic centimeter of filtered gastric juice five centimeters of ether are added, shaken and allowed to stand. To a few centimeters of the iron solution, which is practically colorless, are added several drops of the ether extract, and if lactic acid is present a canary-yellow color will result.

Sclerogenic Treatment of Cancer.—The history of a case of cancer of the breast treated by injections of a 5-per-cent. solution of zinc chloride is related by P. COUDRAY (*Jour. de Med. de Paris,* July 21, 1901). The first injection was made in November, 1891, a second in March, 1892. At these times the solution was injected not only into the breast itself, but into and about the axillary lymph-nodes, which were enlarged. Five years later the breast was atrophied, presenting a vague nodule surrounded by adipose tissue. Nine years after the primary injection there was still no return of the tumor. During the past few months a recurrence has been noted; there is now present a scirrhous growth, adherent to the skin, showing a tendency to ulceration, and accompanied by enlarged axillary nodes. Coudray believes that the growth of cancer may sometimes be arrested for a long period by sclerogenic treatment, and that this arrest is due to the obliteration of lymphatic spaces and vessels.

Propagation of Yellow Fever.—Probably the most valuable contribution to the science of medicine during the past year is the conclusive proof that yellow fever is transmitted from one patient to another by means of the mosquito. Formerly the chief means of communication was thought to be through fomites. J. C. Nott in 1848 was the first to suggest that an intermediate host was necessary to the spread of yellow fever. Full credit for the mosquito theory must be given, however, to C. J. Finlay, although positive results could not be obtained by him. During the past year W. REED (*Fed. Rec.,* Aug. 10, 1901) of the United States Army has conducted a series of most valuable experiments and the results are most reliable and conclusive. At Camp Lazaer, near Quemados, Cuba, one building was erected in which a large quantity of fomites from fatal cases of yellow fever were placed and several persons compelled to remain in the building, which was poorly ventilated, for several weeks without developing any symptoms of disease. Another building was erected, sanitarily clean in every way, surrounded by fine netting and divided into two parts by fine netting also. In one part several *Culex* mosquitoes were placed after they had bitten yellow fever patients and in the other non-immune persons were quarantined. None of these people developed any disease in the

non-infected apartment. The men were then exposed to the mosquitoes, but no results were at first obtained, probably on account of the short interval elapsing from the time of contamination of the mosquito to the day of inoculation. The first positive result was obtained upon a volunteer who was bitten by five mosquitoes which had been previously contaminated, as follows, two fifteen days; one nineteen days, and two twenty-one days. Three days and nine and one-half hours afterward he developed a well-marked case of yellow fever. Several other men were similarly inoculated during the next few weeks and all but two had attacks of yellow fever, beginning from three to five days after being bitten. An important point was settled by experiment with another brave volunteer who was bitten by fourteen mosquitoes on the fourth day after they had become contaminated. The result was negative. He was again bitten on the eleventh day without effect. On the seventeenth day after their contamination he was again exposed to the mosquitoes and on the fourth day thereafter developed a severe attack. Other patients were inoculated by bites from these mosquitoes on their fifty-first and fifty-seventh day of contamination thus showing the length of time during which their bites are dangerous. Four patients were also inoculated by subcutaneous injections of blood taken from those suffering from yellow fever.

Carbon-Disulphide Poisoning in India Rubber Workers.—Two laborers, whose work exposed them to the vapors rising from a vat containing carbon disulphide used in vulcanizing rubber, presented themselves to E. MENDEL (*Berl. klin. Woch.*, July 29, 1901) with symptoms of extreme muscular weakness in forearms, hands and legs. Examination showed muscular atrophy in the distribution of the median, ulnar and radial nerves with partial reaction of degeneration. The absence of tenderness along the course of the peripheral nerves and the lack of disturbances of sensation excluded a neuritis. The clinical picture corresponded more closely with disease of the anterior cornua of the spinal cord. It has been experimentally shown, however, that carbon disulphide is capable of producing disease of almost all parts of the nervous system, and its etiological significance must be remembered in the diagnosis and treatment of nervous disorders in individuals exposed to its action.

Cause and Treatment of Gout.—The theories in regard to the cause of gout are constantly becoming more numerous and many of them are extremely unsatisfactory and unreasonable. The idea of auto-intoxication is offered as a starting-point of so many diseases at present and the intestinal tract has very properly been held responsible for numerous derangements and constitutional diseases. W. R. GORE (*Indian Med. Rec.*, July 10, 1901) believes that gout is not due to the presence of uric acid in the blood, but that the symptoms result from the presence of a toxin which is formed by one of the intestinal bacilli on an intestinal secretion specifically altered by the diet. The object of the treatment, therefore, consists of the selection of a proper diet which will be quickly digested, the refusal of alcohol in any form during treatment and careful attention to the condition of the bowels. The action of two drugs, colchicum and lead, which seem to have a specific influence upon the disease is offered to confirm the theory. Colchicum acts by increasing the secretion of the intestines and may cause some change in the constituents of the secretion. Lead causes a contraction of the blood-vessels of the intestine, decreasing intestinal secretion and favoring gout. The author believes that when gout is treated as due to a toxin caused by intestinal derangement the results are much better than when treated in any other way.

Tabes Dorsalis in Women.—In a series of cases of locomotor ataxia observed by P. FEHRER (*Berl. klin. Woch.*, July 29, 1901) the initial symptoms were as follows: Lancinating pains, 13 cases; weakness in legs and back, 10 cases; headache or dizziness, 8 cases; paresthesia, 6 cases; loss of visual power or diplopia, 5 cases; gastric crises, 5 cases. During treatment the symptoms occurring were, in the order of frequency, disturbances of sensation (92 per cent.), lancinating pains (85 per cent.), loss of patellar reflex (83 per cent.), Argyll-Robertson pupil (76 per cent.), Romberg symptom (71 per cent.), ataxia (55 per cent.), disturbance of bladder and rectum (50 per cent.), gastric crises, inequality of pupils, paresthesia, headache, vertigo, girdle sensation, weakness of extremities, ocular paralyses, optic-nerve atrophy, cardiac neuroses, psychical disturbance, diplopia, laryngeal crises. In the treatment of these cases, antisyphilitic remedies and silver nitrate were practically without result. Amelioration of symptoms was obtained in one-half the cases by exercise and regimen.

A Case of Latent Renal Lithiasis.—A patient of sedentary habits, whose previous history included nothing of interest beyond occasional vague lumbar pains, became suddenly ill, complaining of general lassitude and headache. Physical examination was negative. The urine gave a very faint reaction to the cold nitric-acid test for albumin. There were no definite symptoms of nephritis. Three days later intense lumbar pain developed, with frequent desire to urinate; the lumbar pains persisted. At the end of a week respiratory difficulty, increased rapidity of pulse and galop-rhythm were present. During the night a syncopal attack developed at stool. Slight pyrexia, obscuration of the visual field, cramp-like pains in the legs, intense frontal headache, feeble, rapid pulse, increasing albuminuria, all followed in rapid succession. Sudden death occurred on the ninth day. More than 500 calcium-oxalate calculi were found at the autopsy by DESSIRER and LEGRAND (*La Méd. Moderne*, July 17, 1901). The pelvis, calices and collecting tubules of both kidneys were filled with these concretions. The kidneys themselves had suffered from marked sclerosis.

Cholelithiasis as a Cause of Gastric Disease.—Among 102 cases of benign gastric disease treated surgically in the Heidelberg clinic 12 cases were regarded by PETERSON (*Wiener klin. Rund.*, July 21, 1901) as positively and 5 cases probably due to cholelithiasis. The symptoms were caused by pressure of the enlarged and stone-filled gall-bladder on the duodenum, by injury of the duodenum by a perforating calculus, by pericholecystitis with or without perigastritis, or by the pressure of a large stone situated in either the cystic or common duct. These produced compression or twisting of the duodenum, cicatricial contraction, and band-like adhesions. The classic symptom is stenosis of the pylorus or duodenum; gastralgia occurs at times. Perforation or thrombosis may cause hematemesis. Obstruction may be followed by a loss of free hydrochloric acid and the appearance of lactic acid; the diagnosis of carcinoma is often made. The secondary gastric changes may demand gastro-enterostomy. In any event it is essential to break up adhesions, to remove accumulations of gall-stones, and to provide a free passage for hepatic secretions.

Pneumobacillus and Purulent Cerebrospinal Meningitis.—Up to the present time this bacillus has been found in only a few cases of purulent cerebrospinal meningitis. K. JASSNIGER (*Ctblt. f. Bäk.*, July 12, 1901) cites a case occurring in a patient, sixteen years of age, who was suddenly taken ill with chills followed by a perminent rise of temperature to over 101° F. There were present uncontrollable vomiting, intense headache, general muscular pains, profuse perspiration, irregularly contracted pupils and incontinuance of urine and feces. Coma supervened and death took place on the seventh day. The clinical diagnosis was cerebrospinal meningitis and upon autopsy the characteristic pathological lesions were found. A cover-slip preparation of the meningeal pus stained by methylene blue showed both intra- and extra-cellularly a short, round bacillus, sometimes occurring in pairs. The twenty-four-hour bouillon growth showed a general diffused clouding with pellicle formation. Agar cultures showed a white surface growth and gelatin plates small, round, opaque colonies. Stab cultures in gelatin after forty-eight hours' growth showed a typical development along the line of inoculation. No coagulation was produced in milk. Glucose was fermented. Gram's strain was not retained. The organism was pathogenic for mice in twenty-four hours by intraperitoneal inoculation, capsule bacilli being obtained from their heart's blood. He therefore regards the organism found as identical with Friedländer's pneumobacillus.

Action of Alcohol on the Heart.—New researches are contributed by L. HASKOVEC (*Arch. de Med Experimentale*, July, 1901) who has pursued experimental investigations along this line upon dogs. Small doses (5 c.c. of a solution of 7 parts of alcohol to 25 of water) produced upon intravenous injection a distinct rise in the blood-pressure lasting from six to eight seconds and in some cases even longer. The same result is observed when one has poisoned the peripheral vagus nerve with atropine. Hence he thinks that alcohol acts directly upon the heart, in small doses causing it to produce more work. In such doses it is a stimulant. The greatest increase in the number of pulsations is met with in the state of chronic alcoholic poisoning, probably due to the increased muscular activity and general physical condition produced.

Anthrax; a New Mode for Its Distribution.—There is every reason to suppose that if anthrax is gaining such a foothold in Scotland as one would be led to believe from a discussion of a number of cases by ALEXANDER SCOTT (*Brit. Med. Jour.*, July 20, 1901) there is a good prospect that the general practitioners will come in contact with cases sooner or later. As would be expected, all those cited in this paper occurred among the ill-nourished workers in horse hair. The British veterinary regulations are so efficient as to have secured a total immunity from anthrax to these operations. Very recently, however, due to the importations of Chinese, Siberian and Russion hair, anthrax has broken out in almost epidemic form in the neighborhood of Glasgow. The diagnosis of these cases has in a number of instances proved difficult and has been sadly delayed by the fact that many of them have been on the gastric or pulmonic form in which the symptoms are closely marked and are at best subjective. It is a curious fact that in these varieties of the malady, no large development of the organism takes place in the blood till just before or just after death. The prevention of this disease is not, according to this report, as easy as it might seem. It is ably considered under the following three heads: (1) The dust; the germs are more easily disseminated in the dry state, hence it is of paramount importance that the hairs be kept as wet as possible. (2) The germs; with the vegetative form there is no difficulty, since a temperature of 50° C. for ten minutes destroys it; the spore, however, is next door to salamandoid in its relation to heat; indeed, there is no known process by which it can be destroyed when contaminating hair without the use of agents which work serious damage to the host. The excessive steam pressure necessary to kill the spores cause each hair to curl up at the ends and become utterly inelastic and useless. (3) All hair should, however, be boiled for thirty minutes. If this be done in a two-per-cent. solution of potassium permanganate and if the hair be subsequently bleached by a three-per-cent. solution of sulphurous acid, the author feels that a great deal can be done toward rendering this lithal Asiatic hair harmless. The crying need for immediate action is self-evident. Suppose even that spore-bearing hair finds its way into cushions without infecting any body at the primary handling, there is no reason to believe that they may not kill the innocent who shakes them loose ten to twenty years later.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

DUST AND CHILDREN'S SUMMER DIARRHEAS.

THE summer death-rate in children is always highest, not during the first hot spell when adults as a rule suffer the most, but later in the season after the heat has weakened resistive vitality, so that the end of the month of August usually furnishes the worst statistics in infant mortality. It is well known how sensitive to even slightly noxious agents are the delicate intestinal tracts of infants who have had an attack of gastro-intestinal disturbance early in the summer. If such children are to be saved from the dangers of the summer later on the most careful precautions must be exercised with regard to the admission of even the slightest amount of infectious material into their digestive tracts. It is to be supposed that proper safeguards are taken with regard to their food and drink. Water that may be perfectly innocuous for adults or even children of a larger growth may well contain non-specific germs that will affect the sensitive stomach and bowels of delicate infants. No matter how healthful the water of a locality, it should always be boiled for young children and should not be allowed to stand in open vessels before being used. This precaution is all the more important if, as so often happens, families are not at home for the summer, but are using water the condition of which they know nothing.

Digestive disturbances in children are usually due to crude imperfections in diet or easily recognizable violations of sanitary regulations. Not infrequently, however, it is impossible to determine what has been the active agent in the production of diarrheic disease in a given case. Under these circumstances there is a growing tendency to consider that dust and its attendant dangers have had something to do with the production of the affection. The exposure of food materials destined for children to the chances of dust infection, especially after their preparation is complete, is of course wanton negligence. There are other risks, however, that are not so readily recognized. The use of dusty drinking utensils would be unpardonable, but the danger of contamination of the child's hands and person and the conveyance of infectious material to the mouth in this way has not been generally sufficiently considered. It may seem far-fetched and finical to take serious account of a so apparently trivial source of infection, but infantile health is dependent on the minutest precautions. The triviality of the cause at work will not be insisted on by those who remember how soon and how seriously lead-workers who fail to be cleanly are affected by their occupation. Clean hands mean for workmen, who are not extremely susceptible to the influence of lead, comparative freedom from the symptoms of plumbism. In this case there is question, not of extremely active living toxic principles, but of the gradual accumulation of a comparatively inert metallic substance. The patient in one case is a healthy adult, in the other a delicate child, so that the question of clean hands can be readily understood to be of very serious importance.

Perhaps in nothing has Christian science deservedly incurred more blame than in its treatment of the ailments of children. Sanitary regulations, the value of which has been learned only by costly experience in infant mortality, are calmly set aside because they are a recognition of the existence of evil in the world. The recent declaration of a healer on this subject seems worth quoting, because it emphasizes by contradiction the measures that are most necessary for the preservation of infantile health during the summer weather. "The condition of the stomach or bowels," she said, "and its food and clothing are of no serious moment to your child. The daily ablution of an infant is not more natural or necessary than to take a fresh fish out of

water and cover it with sand once a day that it may thrive better in its natural element." This represents the very acme of delusional absurdity. Such an opinion makes still more striking a recent expression with regard to Christian scientists by a writer in the *North American Review*. He says that the adherents of Eddyism illustrate better than ever before in history "how near the verge of insanity persons may wander and still retain financial ability."

After the care of the child's food the most scrupulous care for its personal cleanliness constitutes the best safeguard against the development of gastro-intestinal disturbance. After every outing and before every feeding the infant's hands and face should be cleansed conscientiously. The dangers of contamination by dust particles that cling to the hands and face to find their way eventually into the mouth are by no means so negligible as might be imagined. In the course of prophylactic progress that has become so marked a feature of medical advance in recent years this factor in pathogenesis must be taken into account if we are to continue our reduction of infantile summer mortality and not merely be satisfied with what has been accomplished.

FREE PUBLIC BATHS.

Reading in the head-lines of one of the recent daily papers, "New Jersey Farmers Get Their Yearly Bath," one may be inclined at first sight to yield the smile which the writer hoped to win. A second look shows that the article merely recounts the celebration of the annual "Big Salt Water Day" by the farmers near the New Jersey coast and their antics upon the occasion. There was no apparent intention of aspersing the customs of the Jerseymen.

Coming nearer home the suggestion of a yearly bath is one savoring less of wit than of pathos. Who that has ministered to the inmates of the city's tenements has failed to find an explanation of their apparent antipathy to water if he has entered their homes? If the tenement is one of a higher grade an iron sink is found in each apartment; if of the lower class, one is placed in each hall for the two or four families occupying the floor. And this is what is provided to encourage that cleanliness which is said to be next to godliness and which goes so far in the prevention of disease! With a large family packed in a few small rooms it is little wonder that ablutions are confined to the face and hands. Ventilation the owners of tenements can and must provide, but plumbing is expensive, and the installation of baths would place the cost of the poorer grades of tenements out of the reach of those whose limited means force their occupation of this class of dwelling.

The provision of bathing facilities in these houses themselves being obviously beyond the limit of what may reasonably be expected, public baths are the natural solution of the difficulty. The recommendation of Commissioner Kearney that the city construct eleven public bath-houses, five of them to be placed in Manhattan, is a step in the right direction and deserves the support of every physician. There are, of course, some of the more newly-acquired citizens of this growing land of freedom who have an inherited fear of ablutions, but with facilities at their command it is likely that although the present generation may be hopelessly grounded in its dread of water, the characteristic might be eliminated in the next. No stronger sign of the appreciation of the public can be needed than the weekly attendance at the Rivington Street Public Bath, which is set down by Mr. Kearney as thirty thousand.

INTERMEDIATE TYPES OF DISEASE.

Long ago in the columns of the *Century* Uncle Esek said very well, "It is not so much the ignorance of mankind that makes them ridiculous as the knowing so many things that ain't so." The expression sums up in a few pregnant words a very prevalent state of the human mind of which the physician has especially to be careful. Most of the medical practitioners of every generation have been perfectly "cock sure" of a number of things that the next generation of physicians (and surgeons) have learned to look on as absurd. It would be almost childishly naive to hope that our generation is to be saved from the pitfalls of false opinion, and so we may be sure that at least a certain number of our present-day cherished ideas will loom up before we shuffle off this mortal coil as the not easily explicable errors of deficient knowledge.

Our dogmatism is manifest in this present generation in nothing more than in the labeling of disease types. We call a disease rheumatism and then seem to think that we have definitely classified it. We call a condition cirrhosis of the liver and are apt to feel that that ends the matter. There are hopeful signs, however, of growing dissatisfaction with accepted types of disease. From many sides we are learning what manifold conditions may be included under the term rheu-

matic. Not only are there variants according to the acuity or chronicity of the disease, but also in the cause of the underlying pathological condition. A very helpful book has been recently written on "Some Cirrhoses of the Liver" in which the author frankly admits our ignorance of the various forms of sclerotic disease of the hepatic gland, while making clear that their name is probably legion.

Perhaps in no department of nosology are we less ready to admit the possibility of further development in differential diagnosis than in the acute exanthematous diseases. There is a universal and very definite impression that, at least in the matter of eruptive disease, medical diagnosis has attained precise and unalterable limits. Recent investigations, however, go far to disturb this apparent finality. Within the last ten years the medical world generally has come to admit the existence of an independent type of exanthematous disease in what is known as German measles, though why the adjective German should be employed rather than any other national epithet is not very clear. Last year an English physician described an epidemic of "a fourth disease," that is to say, he found that under the term "rubella" or German measles two diseases were confounded, neither of them identical with scarlet fever or measles. This observation needs substantiation by other investigators, but it serves to show very well the spirit of the times and the encouraging skepticism as to the absoluteness of present-day types of disease.

As a matter of fact it would not be surprising if there were many more distinct exanthemata than those now recognized. It is a subject for wonder that the skin should react with such characteristic difference to what are, after all, very similar irritants, but, since it does react differently, the limit of its variability under conditions of irritation is hard to set. There are said to be some eleven different kinds of nut-galls produced by the sting of insects in this country alone. Each form of gall is produced only by one special kind of insect and the cells of the tree react differently to each ovipositor. The more highly specialized cells of the human skin might well be expected to give many types of eruption as a consequence of specific irritants.

That we have not as yet all the important exanthemata finally classified seems sure. One of the largest and most important groups of exanthematic infectious fever is embraced under the term smallpox. There is a growing impression that there is included under this head more than one type of disease. Many believe that there is an intermediate disease between varicella and variola. Some examples of this type of disease, for which vaccination proved no protection and immediately after which vaccination was successfully performed, were described at the sessions of the American Medical Association last year. It remains to be seen whether such an intermediate type of disease does not really exist. Some excellent opportunities are just now afforded students of smallpox here in the East for the detailed study of the disease. Let us hope that the chances provided will not be missed and that the present epidemic will at least bring us definite knowledge on these disputed points.

ECHOES AND NEWS.

NEW YORK.

Modified Smallpox Epidemic.—Middletown, N. Y., is suffering from a mild epidemic of modified smallpox or an intermediate disease between this and chicken-pox.

Navy Yard Garbage Washes on the Beaches.—Many complaints have recently been made regarding the pollution of the shores of Bay Ridge and contiguous territory with garbage. Investigation has shown that the Government scows which carry refuse from the Navy Yard contribute more than their share to this nuisance. Formerly the refuse of the yard was burned in the crematory, but for some unknown reason this has been discontinued.

Vaccinators Reinstated.—The Health Department has reinstated the forty extra medical inspectors who were employed to vaccinate school children and who were suspended two weeks ago because the Civil Service Commission declared that they were not entitled to the pay they were drawing. The men were simply hired from month to month and received $100 per month each as salary. The Civil Service Commission declared that the men were entitled to but $600 per annum and to receive $1,200 a year without competitive examination was a violation of Rule 37 of the Civil Service rules, and the Health Department was forced to dismiss the additional vaccinators. Rule 37 is: "An increase in salary or other compensation of any person holding an office or position within the scope of these rules beyond the limit fixed for the grade in which such office or position is classified, shall be deemed a promotion."

Results of Dr. Doty's Mosquito Campaign.—Dr. Doty has issued a report on his experiments in mosquito destruction at Concord, Staten Island. After referring to experiments in various parts of the world which proved that

the malarial parasite was transmitted from one person to another by the female of the *Anopheles* species of mosquito, the Health Officer of the Port says that he found at least 30 per cent. of the inhabitants of Concord suffering from either acute or chronic malaria. "In almost every house or yard were found typical breeding-places for mosquitoes," he writes, "either in the shape of used or unused rain barrels, cisterns, cesspools, or abandoned receptacles thrown about the premises. Samples of water from these, as well as all stagnant pools, were examined, and the larvæ found. In some instances, particularly in receptacles about the house, the water was actually alive with them." Of twenty-seven mosquitoes taken from a bedroom, more than one-half were malarial insects. The stagnant pools in the Concord district and the weeds surrounding them were treated with oil and relief was felt by the inhabitants. Dr. Doty concludes that the use of petroleum as advised by experts bears out the claims made by them.

PHILADELPHIA.

Statue of "The Medicine Man."—The bronze equestrian statue of "The Medicine Man," by Cyrus E. Dallin, has arrived from Paris and been formally accepted by the Fairmount Park Commissioners. The Austrian Government had authorized its purchase for Vienna before it was known that Philadelphia had secured the statue. It will be mounted on the summit of Strawberry Hill, Fairmount Park.

Insane Asylums Overcrowded.—The institutions which suffer the most by Governor Stone's reduction of appropriations are probably the State insane asylums. The asylum at Harrisburg is most in need of improvement, the State Board of Charities asking for an appropriation of $498,000 for two years. This was cut by the Legislature to $256,000 and the Governor further reduced it to $136,000. The capacity of the buildings is about 700 and there are now 879 inmates. The result of the cut in appropriations means that many of the additional insane for the next two years will be sent to county homes and detained as paupers with pauper care.

Smallpox Hospital Looted.—The smallpox hospital at Gloucester, N. J., was recently robbed of the beds, bedding, chinaware, supplies, etc.

Resignation of Dr. Taylor.—Dr. J. Madison Taylor, for fifteen years professor of diseases of children in the Philadelphia Polyclinic, has tendered his resignation.

Deaths from Gasoline Explosions.—The explosion of gasoline August 5th which wrecked five houses, caused the death of eight people, and seriously injured a dozen more, has caused unusual activity among the city officials in searching for other places where that material is illegally stored. A special license must be owned if more than one gallon is kept. The insurance patrol records show that since 1895 there have been 120 explosions from gasoline in some of its forms.

Large Bequests to Charities.—The will of Emily Phillips, who died July 24th, leaves a large portion of the estate of $400,000 to charitable institutions. Among the bequests are Jefferson Hospital, $10,000; Jewish Hospital, $40,000; Pennsylvania Hospital, $4,000. The Presbyterian Hospital receives $2,000 and the Medico-Chirurgical and Howard Hospitals $1,000 each.

Typhoid Fever Again Prevalent.—For the week ending August 10th there were reported 117 cases of typhoid fever, an increase of 25 over the preceding week. Until the latter part of July the present year showed a much smaller number of typhoid cases than during the epidemic of 1899. Of late the records about equal those of two years ago, although a repetition of that epidemic is not feared at present.

University of Pennsylvania.—Dr. C. J. Essig has resigned the professorship of mechanical dentistry and metallurgy in the Dental Department of which he was the founder in 1897 and its first Dean. Under his management it became the most successful department, financially, in the University.

CHICAGO.

College of Physicians and Surgeons, Chicago.—This institution has recovered from the effects of its recent fire and is now in excellent running order for the fall term.

Infant Mortality Reduced.—Infant mortality has been so reduced and sanitary conditions have been so improved as a result of the labors of the volunteer medical inspectors that Dr. John R. Neeley has decided to issue a call for fifty more physicians and nurses. When the new volunteers enlist the inspection, instead of being confined to the Ghetto and other crowded tenement districts, will take in other parts of the city where insanitary conditions may be ameliorated.

Graduate Nurses Organize.—The work of organization in the Graduate Nurses' Association of Illinois has been completed. A constitution has been adopted and steps taken for the incorporation of the Association. The object of the organization is to secure State recognition for trained nurses in the same manner that physicians and pharmacists are legalized.

Need of Isolation Hospitals in Chicago.—Dr. Heman Spalding, Chief Medical Inspector of the Health Department, discusses this subject in a recent issue of the *Chicago Tribune*. Among other things he says: "Chicago has a well-equipped isolation hospital for smallpox of which every citizen may be proud, but the city has long needed isolation hospitals for diphtheria, scarlet fever, measles, whooping-cough, and tuberculosis. These isolation hospitals are necessary for those who have no

means at home for the proper care and precautionary measures necessary to prevent the spread of contagion. Almost daily scarlet fever and diphtheria are found in families where other members of the family have no escape from disease. An example of the efficacy of the removal and isolation of persons suffering with a communicable disease is found in our experience here in Chicago in suppressing smallpox. During the recent outbreak of smallpox throughout the country many persons afflicted with the disease in all its stages have come to the city from various States and mingled with others before their presence was known to the Health Department. The prompt removal to the hospital of all persons afflicted with smallpox has enabled the Department to keep the disease from gaining a permanent foothold in Chicago. The other infectious diseases could be stamped out with even less difficulty if the same methods used for smallpox were pursued in cases where safety could not be secured in the home. Is there not some way to secure isolation hospitals for epidemic contagious diseases not now provided for? The city should build and own them, but the money is not in sight. The millionaire philanthropist sees more attractive fields in aiding those who are not helpless by endowing colleges and fitting up libraries. If the Chicago University will build these hospitals in connection with the medical department of the Rush Medical College, it will be a stroke of wisdom furnishing unlimited rare clinical material for teaching. Such a hospital could be made self-supporting, as many able to pay would seek isolation and treatment there. It would be a place where the stricken hotel guest could go, when to remain would be a source of danger to others and the cause of financial loss to the landlord."

Chicago Eye, Ear, Nose and Throat College.—This institution, which recently moved into its new building, offers to practitioners of medicine the very best facilities for acquiring proficiency in physical examination, diagnosis and treatment of diseases in these very important departments of medicine. The college is located at 206 East Washington Street. Instruction is both clinical and practical. The college is thoroughly equipped in every respect, particularly in the way of instruments and apparatus, which are as essential as a fine building. It has a limited number of free beds and operations, board and nursing are furnished. These beds are much in demand and often booked in advance.

Transfer of Preclinical Work of Rush Medical College to the University of Chicago.—It is believed that this transfer marks a distinct step forward in medical education in this city. This combination, more intimate and satisfactory than has hitherto existed between the interests of the University, will prove to be of incalculable benefit to both. The present transfer, it is hoped by many, represents only a partial realization of the possibilities of combination which the common interests of Rush Medical College and the University of Chicago suggest. Conditions are changing with the times, and the factors which prevented the close proximity of hospital and university in large cities are rapidly disappearing; indeed, they may be said no longer to exist.

New Clinical Amphitheater.—At the Mercy Hospital a magnificent surgical and clinical amphitheater is in process of erection; it will cost $25,000. Its seating capacity will be 400, and no seat is over nine rows from the operator. Tile, marble, glass and every modern arrangement will be employed to make the surgical schoolroom a model of its kind. The expense is being met very largely by the Northwestern University Medical School and its use will be confined to the Faculty of this school.

Internes Forbidden to Perform Operations at the Cook County Hospital.—Internes at the County Hospital are henceforth barred from performing major operations. Warden Healy has issued the most stringent order ever posted in the operating-rooms of the hospital. This order went into effect August 5th and reads as follows: "Under no circumstances shall any interne be allowed to perform a major operation or high forceps delivery, either with or without the presence of the attending surgeon. In any case of emergency the house physician or surgeon shall secure the immediate attendance of the attending physician or surgeon. This rule covers all operations where it becomes necessary to place patients under anesthetics. Any violation of this rule will subject the offender to immediate suspension from the hospital force." In consequence of this rule internes are up in arms against the Warden. They protest that they are at the hospital for the experience they gain in the operations there performed, and that without the chance to operate they learn very little. But Mr. Healy will not change the order nor in any way modify it. For a number of years it was the rule that all major operations must be performed by the staff surgeons, and internes were not permitted to do the work. This rule was not rigidly adhered to, with the result that many operations were done by the internes themselves, and the number of these operations kept increasing with unsatisfactory results.

GENERAL.

American Veterinary Medical Association.—The thirty-eighth annual meeting will meet at the Hotel Rudolf, Atlantic City, N. J., September 3, 4, 5 and 6, 1901.

Canadian Medical Association.—The thirty-fourth annual meeting of this Association will take place at Winnipeg, Manitoba, August 28-31, 1901. An interesting program is promised.

Mississippi Valley Medical Association.—The next annual meeting of this Association, to meet at Put-in-Bay, offers the following program: Address in Medicine, by Frank Billings, Chicago; Address in Surgery, by Reginald H. Sayre, New York City; Address of President, A. H. Cordier, Kansas City, Mo.; Pathological Cause of the Eruption in the Exanthemata, by J. M. Postle, Hinckley, Ill.; Acute Intestinal Auto-infection, by John M. Batten, Downingstown, Pa.; Surgery of the Palate, with Stereopticon Exhibit, by Truman W. Brophy, Chicago, Ill.; Some New Remedial Agents in the Treatment of Gynecological Affections, by Chauncey D. Palmer, Avondale, Cincinnati, O.; Surgical Treatment of Pulmonary Abscess, by D. N. Eisendrath, Chicago, Ill.; The Severing of the Vas Deferens and Its Relation to Neuro-Psycopathic Constitution, by H. C. Sharp, Jeffersonville, Ind.; Varicose Veins and Their Treatment, by J. Lively Johnson,, Louisville, Ky.; Subdural Hematoma from Pachymeningitis Hemorrhagica Interna, by Charles J. Aldrich, Cleveland, O.; Some Obscure Injuries Which Follow the First Toxic Action of Alcohol, by T. D. Crothers, Hartford, Conn.; Sterilization of Rubber Gloves, Catheters, etc., by Formaldehyd Gas; Correct and Erroneous Culture Tests, by A. Goldspohn, Chicago, Ill.; Auto-intoxication and Its Treatment, by Chas H. Shepard, Brooklyn, N. Y.; Aboriginal American (Indian) Contribution to Therapeutics, by B. T. Whitmore, New York City; The Bed-treatment of the Insane, by Frank Parsons Norbury, Jacksonville, Ill.; The Clinical Diagnosis of Carcinoma of the Esophagus and the Technic of Gastrostomy, by Charles G. Cumston, Boston; Clinical Notes on Gleet, by A. Ravogli, Cincinnati, O.; Dentists' Neck, a Hitherto Undescribed Neurosis, by Albert E. Sterne, Indianapolis, Ind.; The Value of Mechanical Appliances in the Aid of Intestinal Suture, by Edward H. Lee, Chicago, Ill.; A Discussion of the Morbid Conditions of the Upper Respiratory Tract Resulting from the Infectious Diseases, by Colus M. Cobb, Boston, Mass.; Congenital Valvular Obstipation, by Thos. Chas. Martin, Cleveland, O.; Features Determining Permanency of Cure in Radical Operations for Hernia, by A. J. Ochsner, Chicago; Science and Christian Science, Their Claims and Miracles, by Paul Paquin, Asheville, N. C.; Gastric Lavage, Its Uses and Abuses, by Thos. Hunt Stucky, Louisville, Ky.; Some Causes of Ignored Syphilis and Their Remedies; Clinical Examples Demonstrated from Lantern Slide Reproductions, by M. L. Heidingsfeld, Cincinnati, O.; A Few Cases of Hysteria, by Hugh T. Patrick, Chigaco, Ill.; A New Method of Controlling Hemorrhage in Operations upon the Head and Neck, by George W. Crile, Cleveland, O.; Tripartition in the Study of the Female Pelvis, by A. Ernest Gallant, New York City; Scientific Aids to Diagnosis, by Henry D. Holton, Brattleboro, Vt.; How Should Appendicitis Cases be Treated? by Joseph Price, Philadelphia, Pa.; A Case of Unilateral Fulminating Optic Neuritis Cured by Trephining the Sphenoidal Sinus, by J. O. Stillson, Indianapolis, Ind.; The Surgical Features of Typhoid Fever and Dysentery, by Hal. C. Wyman, Detroit, Mich.; Surgical Intervention in Pulmonary Abscess, with Illustrative Cases, by W. J. Macdonald, Albany, N. Y.; Report of One Hundred Cases Operated for Appendicitis, by Wm. J. Gillette, Toledo, O.; The Surgical Treatment of Diseases of the Stomach, by A. Vander Veer, Albany, N. Y.; Some Indications for Gastro-enterostomy, by Wm. J. Mayo, Rochester, Minn.; The Young Doctor, by Emil Amberg, Detroit, Mich.; Fractures, by E. B. Smith, Detroit, Mich.; Cancer of the Uterus, by Louis Frank, Louisville, Ky.; Floating Liver, with Report of Case, by J. H. Carsters, Detroit, Mich.; The Acquirement of Nervous Health, by F. Savary Pearce, Philadelphia, Pa.

Danish Prizes for Science.—Two of the Nobel Institute's scientific prizes, each worth 20,000 Danish kroner, have been awarded, one to Dr. Finsen, the originator of light treatment for lupus, and the other to Dr. Pavloff, a Russian physiologist, for his researches in nutrition.

Yellow Fever Serum.—It is reported that a government commission has been appointed to investigate the claims of Dr. Caldas as having discovered an efficient yellow fever serum, both curative and prophylactic.

Obituary.—Dr. William A. Newell, Governor of New Jersey from 1857 to 1860, died at Allentown, N. J., August 8th at the age of eighty-four. Dr. Newell graduated from the University of Pennsylvania in 1841 and had practised medicine since with the exception of the years he was chief executive of New Jersey.

Intelligence of the death of Dr. Herman Armgardt of 317 Leonard street, Brooklyn, was received last week from Hamburg, Germany, by his relatives. Dr. Armgardt was fifty-two years old. He came to this country when he was eighteen years of age and studied medicine. After living in Chicago for some years he returned to New York and settled in the Fifteenth ward, Brooklyn, where for over twenty years he had a large practice.

Dr. Thomas Sappington, who practised medicine in Frederick County, Maryland, and Baltimore for more than fifty years, died Monday, August 12th. He was the son of Col. Thomas Sappington, of Frederick County, an officer in the army during the war with England in 1812. He was born in Libertytown, Frederick County, on October 26, 1816. He was educated in the county schools and began to study medicine in Baltimore, but owing to certain differences among the faculty at the University of Maryland School of Medicine, he, with a number of other students, left and went to Philadelphia. He entered the University of Pennsylvania and graduated from that school in 1839.

CORRESPONDENCE.

REPLY TO DR. MC MILLAN.

To the Editor of the MEDICAL NEWS:

DEAR SIR: The action of the American Medical Association in recommending the reinstatement of the army canteen seems to have aroused the antagonism of hundreds (?) and perhaps thousands (??) of physicians, according to our worthy contemporary, Dr. D. I. McMillan of Sunbeam, Illinois and he, it seems, has been appointed to voice the sentiments of thousands whose deep-tongued bay sounds "Beware!" (See MEDICAL NEWS, June 22, 1901.)

In the battles of the world great generals are matched against great generals and petty officers pitted against their like, so that I may be pardoned when I take up the defense of the American Medical Association *versus* McMillan.

To see such a grand and noble body, whose name stands for all that is best in medicine, demean itself by noticing the bark of the champion of "anti-canteenism," would indeed be humiliating. But as Louisville, Kentucky, is *small* in comparison to Sunbeam, Illinois, and as the writer plays a small part in the affairs of Louisville's five hundred physicians, he feels that the contest (?) is worthy of his unwieldy efforts.

Seriously considered, the question involved is the choice between two evils, and, as the body politic, we should choose the lesser. The best is always that which benefits the greatest number of people, and if we can have an army canteen where our soldiers may obtain pure and unadulterated liquors in moderation, surely we have taken a step in the right direction.

That the American Medical Association carefully weighed the evidence for and against the canteen cannot be doubted by any familiar with the life-work of its foremost members, and that before taking action upon such a question it fully realized that whatever position it took there would be the usual "hue and cry" of partisans for some other *"sure remedy."*

That the Association has *pitted* itself against "the Christian sentiment of the country" I make bold to deny, but, if that Christian sentiment is such that it stigmatizes without thorough investigation and painstaking study of the situation as *it is*, then the time has come for the Association *to pit* itself against the fanaticism and prejudice of so-called "Christian sentiment."

I may not be as cognizant as the gentleman from Sunbeam, of the "doings" of the fifty canteens of Chickamauga, nor as conversant with the same at Manila, but this I *do know* that the medical men of our army and the army officers themselves now fully realize the mistaken kindness in abolishing the canteen.

I don't believe that even our worthy colleague of the opposite party would dare to impugn the motives of these men who ask for the reinstatement of the canteen, so let us hope that its reestablishment will be another step to the attainment of the American soldier's health, strength and mortality.

DUNNING S. WILSON, M.D., PH.D.

Louisville, Ky., June 30, 1901.

OUR LONDON LETTER.

(From Our Special Correspondent.)

LONDON, August 3, 1901.

THE ANNUAL MEETING OF THE BRITISH MEDICAL ASSOCIATION—THE PRESIDENT—THE ADDRESS IN MEDICINE—THE ADDRESS IN SURGERY—THE SECTIONS—THE RECONSTITUTION OF THE ASSOCIATION—ITS FUTURE.

DURING the past week the British Medical Association has been holding its annual carnival at Cheltenham. Cheltenham used to have a great reputation in bygone days as a fashionable spa, especially favored by Anglo-Indian nabobs whose faces were as yellow as the gold they had brought from the East, and it still has about it an air of faded gentility from the number of half-pay generals and colonels and ancient dames of more or less high degree who haunt it. The best title of Cheltenham to present fame, however, is the fact that it is the seat of a well-known school for boys and a fine college for ladies. In the buildings of the latter institution the meetings of the British Medical Association were held. All the omens were favorable. The weather was delightful, the arrangements were good, and the occasion was of special interest as the proposed scheme of reform was to be discussed. There is always a large element of picnic in these annual gatherings, and probably as many members attend them for the sake of the dinners, garden parties, excursions to places of interest in the neighborhood and the miscellaneous junketings which result from the meeting of old friends, as for scientific edification. At Cheltenham ample provision was made both for amusement and for instruction, and the meeting was in both respects a success. The number of members present, though an infinitesimal fraction of a body which boasts a membership of some 19,000, was above the average attendance at the annual meetings.

The President of the British Medical Association is always chosen from among the medical practitioners of the place where the annual meeting is held. Hence unless the place be a large city with a university or at least a medical school, the President is generally a worthy man whose reputation is bounded by the confines of the town in which, like the Apostles, he fishes for men—not disdaining to gather women and children, too, into his net. The President of the British Medical Association—universally known and called (as the lawyers say) in the profession here as the "B.M.A."—for the year is Dr. G. B. Ferguson of Cheltenham, who as a graduate of Oxford has more general culture than is often found in provincial doctors in England. His oration was full of quotations in Latin, Greek, French,

and German, and ranged, as such discourses always do, over the whole universe of things medical. It ended with the statement—startling, indeed, as heard from the lips of a doctor—that "there is no death." Lest it should be thought that the President of the British Medical Association is a disciple of Mother Eddy, I hasten to explain that the words were quoted from Longfellow, and were therefore to be understood only in a Pickwickian sense.

Dr. James F. Goodhart, who was formerly physician to Guy's Hospital, delivered the "Address in Medicine." He is one of the few men in the profession who dare not only to think for themselves but to utter their thought. He is always tilting at some medical superstition. This year he had a good deal to say about what he called the "morbid readiness" of medical men to detect disease. They fix too high a standard of health for the great vital organs and condemn all who fail to come up to this artificial standard to a life of needless and harmful invalidism. "Many a one," he said, "who coddles a weak heart dies of real disease which an indolent habit has produced." The the term "catarrh of the stomach" is according to Dr. Goodhart too much on the lips of physicians as well as patients. The stomach is a good, strong, healthy servant, with possibly a prejudice or two; but if treated fairly it is most obliging and thorough. If its master from want of consideration offends it, the estrangement is only "a little domestic concern that wants no third party, such as rhubarb or creosote or salol, may be, to rub the injustice in. A little carbonic acid to soothe its ruffled feelings, and a kindly sorrow and repentance on the part of the master, with a penitential fast, and things will soon come right." Dr. Goodhart also expressed skepticism as to the "dilatation" of the stomach which is at present fashionable, and spoke very plainly as to the craze that has got hold of the public for operative treatment of real or supposed "mobilities" of internal organs. Throats and noses also "suffer terribly from this lust of operation which has beset the public." In reference to another craze, that of overdrugging, Dr. Goodhart quoted a pregnant saying of the late Sir William Gull. Once when a doctor excused himself for not having discovered the existence of a particular disease, that sententious pundit of physic remarked that it was as well he had not done so, for if he had he might have treated it!

The "Address in Surgery" was delivered by Sir William Thomson of Dublin, who did good service in South Africa as consulting surgeon with the forces, and who therefore naturally took as his subject the surgical lessons of the war. He referred with admiration to the results of American surgery in the Cuban and Philippine campaigns, and concluded with a warm tribute to the work done by our medical officers in South Africa. "They have not," he said, "flinched in danger on the field, and they have vied with their combatant fellows in deeds of valor. Six medical officers have been killed; 9 have died of disease; 12 have been wounded; 3 civil surgeons have been killed; 11 have died of disease; and 5 have been wounded. Of all branches, including orderlies and nurses, nearly 400 medical helpers have fallen victims to their labors."

Of the work of the Sections only a word or two need be said here. In the Section of Medicine there was a discussion on "Chronic Diseases of Joints, usually comprised in the terms chronic rheumatism, osteo-arthritis, and rheumatic gout, which brought out a considerable difference of opinion and led to no particular conclusion. In the proceedings of the Section of Surgery the kidney bulked large; while in that of Obstetrics, miscarriage and abortion formed the *pièce de resistance*. In the Section of State Medicine the discussions were for the most part of parochial rather than of general interest. The work of the Sections furnishes a good indication of the trend of medical thought at the time of meeting. It is interesting, therefore, to note that the Sections in which most general interest appeared to be taken were those of Naval and Military Surgery, and of Tropical Diseases. In the former the treatment of the wounded in naval warfare was discussed, and a pretty general feeling was expressed that, under the conditions now existing in British warships, treatment in accordance with the principles of modern surgery was always difficult and often impossible. In the Section of Tropical Diseases a discussion on Stone in the Tropics was opened by Mr. P. J. Freyer, formerly of the Indian Medical Service and now of London. A certain extra-surgical celebrity attaches to the name of Mr. Freyer as the recipient of one of the largest fees in the history of medicine. For attendance on a native Indian prince he was paid a sum of $50,000. The Indian Government which professes to "protect" native princes invited the fortunate surgeon to disgorge, but he preferred to retire from the service with his booty. Dr. Manson (to whom the Association has just awarded the Stewart prize of the value of $250), pointed out that two causes of stone were definitely known, namely, incrustation around a foreign body and around the ova of the bilharzia. He held that the causation of stone should be looked for in the light of a parasitic theory.

The chief interest of the meeting, however, lay in the consideration of the proposed scheme of reform of the constitution of the Association. The principle of the scheme—of which it need only be said here that its fundamental idea is to give greater facilities to the members at large to express their views on any question either of medical politics or the administration of the Association—was adopted, and the consideration of the details was referred to a Committee which is to present a report to a special general meeting to be held in October. At this meeting the proposed reforms will have to be accepted by a two-thirds majority; hence it is possible, though scarcely probable, that the scheme may be shipwrecked within sight of port. The most important part

of the reform from a practical point of view is that all members are to be compelled to belong to a Branch, and for this privilege they are to pay an increased subscription. At present a very large proportion of members are "unattached," and many of these have no desire for the privilege which it is proposed to thrust upon them. If, as is not unlikely, a large body of unattached members were on this ground to withdraw from the Association, a strain would be put on its vitality which even its amended constitution might not enable it to endure. What makes the situation still more risky is that the reformers show a decided tendency to embark on a largely increased expenditure. If the income is materially diminished by the secession of a large number of members, it will not be surprising if the B.M.A. splits into a number of independent—and insignificant—societies, and the reformers will have the satisfaction of feeling that by meddlesome treatment they have killed a useful institution. How little they reck of the financial element in the question was well shown at the meeting. Mr. Butlin, surgeon to St. Bartholomew's Hospital and a former treasurer of the Association, raised a voice of warning as to the proposed increase of expenditure; but none of the speakers who followed him thought it worth while to make any reference to the subject. Thus, as Falstaff says, doth wisdom cry out in the streets and no man regards it.

It will be interesting to watch the future of the Association. So far its history has been a record of almost uninterrupted prosperity and expansion. By a curious coincidence one of the earliest of its annual meetings was held at Cheltenham in 1837, the year of the accession of the late Queen Victoria. On that occasion its membership was under 1,000; now it is 19,000 with branches all over the British Empire. Of these 19,000 probably not more than 1 or 2 per cent. care a jot about the reform of the Association or about medical politics in any form. It is thought by some ardent spirits that the new order of things will breathe life into this huge inert mass and make it active in public work. Enthusiasm can do almost as much as the faith that moves mountains. But the age of miracles is past, and the transformation of the medical profession of Great Britain into a living political force would be nothing less than a miracle. Time, "the subtle thief of youth," may also be trusted to steal from the hearts of our reformers much of the enthusiasm which now throbs in them with so full a pulse of eager hope.

TRANSACTIONS OF FOREIGN SOCIETIES.

French.

RACHICOCAINIZATION—FRACTURE OF THE SKULL AND THE CEREBROSPINAL FLUID—THE BLOOD-SERUM IN TUBERCULOSIS—ACCIDENTAL DEATH BY COCAINE.

M. BROCA, at the Société de Chirurgie de Paris, July 3, 1901, presented a report of a fatality following rachicocainization from M. Prouf (Morlaix). The patient was a woman, sixty-two years old, with a foreign body in her foot. Under the usual precautions and in the approved manner, a centigram of cocaine was injected and the operation was satisfactorily performed. The patient was able to walk home unaided. About one hour after her arrival most alarming symptoms supervened and defied all treatment. Death occurred nineteen hours after the injection.

M. NÉLATON stated that he had seen a similar case in which the symptoms were respiratory and necessitated artificial respiration for fully three hours. For these untoward phenomena the cocaine had been unjustly blamed. The pharmacist of the hospital examined the solution and found it contained a substance which could provoke these signs.

M. CHAPUT endorsed his own custom of withdrawing a small amount of the cerebrospinal fluid before making the injection of the cocaine. Such a technic usually obviates the headache so often complained of by the patients. He has also had the satisfaction of controlling the nervousness of the patient by an injection of morphine a few moments before injecting the cocaine.

M. GUINARD has found great advantage in using the cephalorachidian fluid withdrawn as the vehicle of the cocaine injected. It tends to lessen the cephalalgia to a marked degree. Further, when such pain is present in intense degree he finds it will cease if some of the fluid is drawn off by a lumbar puncture.

M. SEGOND has had four experiences with rachicocainization and is not satisfied with its general usefulness. Two of his injections succeeded. The third failed of anesthesia, but excited grave cephalalgia. The fourth gave perfect anesthesia for an amputation, but within a few hours the patient was attacked by severe pains and an alarming pallor.

M. RECLUS did not believe in any variations in the numerous preparations of cocaine. If there were any solutions containing toxic substances it does not seem likely that he could possibly have escaped receiving and using them in an active minor surgical practice of over fourteen years during which he has generously employed the drug. He has abandoned the use of it in the spinal canal, because it so often excites severe headache.

M. TUFFIER stated that before cocainization of the spinal cord should be condemned on the count of fatality it will be necessary to obtain a full and impartial report of all the deaths from chloroform since the beginning of the discussion of rachicocainization.

M. RENDU, at the Société Médicale des Hôpitaux, July 5, 1901, related an observation he made of a man, forty-six years old, who was brought to the hospital in a state of unconsciousness. Later he showed a right-sided hemiplegia and an aphasia, making one think either of an area of softening due to a thrombosis of one of the vessels of the fissure of Sylvius or of a meningitis of localized character. He succumbed a few

days later in a coma after a series of epileptiform seizures. At the autopsy a fracture of the vault of the skull was laid bare; nothing during life had served to indicate it. It was situated in the right temporal fossa and extended forward to the frontal bone. In addition, there were present two intracranial hemorrhages, one on each side, one beneath the pia mater and the other between the dura and the pia. Where the pia had been stripped off the brain substance was much softened. A lumbar puncture during life had given a rachidian fluid slightly tinged with blood, although the quantity in the skull had been considerable. The explanation of this might be its site far up in the vault of the skull. A cytological examination of this fluid had revealed a very marked lymphocytosis.

M. WIDAL said that such discoveries show that the cytodiagnosis of the cephalorachidian fluid is of value not only to the physician but also to the surgeon. He has often demonstrated to himself that whenever the meninges are the seat of a chronic irritation, however slight, a marked lymphocytosis occurs within the cerebrospinal fluid. Although this has no specific diagnostic import, it serves to show in a general way what the conditions are. Since it seems to be without any exceptions it may serve to clear up the question as to whether or not the meninges are affected.

M. WIDAL also read a paper on the subject of the presence of *sensibilisatrice* in the blood-serum of tuberculous subjects specific like that found in the blood of enterics. In his experiments he used the method of fixation recently set forward by Bordet for the bacilli typhosi and other microbes. Every one is aware that in ordinary media the bacillus of tuberculosis creates pellicles and scales which resist solution in ordinary ways. To obviate this inconvenience he adopted with M. Le Sourd a culture rendered homogeneous by the methods of d'Arloing and Courmont. In order to be free from the glycerine and other clarifying agents contained in their bouillon they subjected the culture to the centrifuge for fifteen or twenty hours and then drew off the bacilli. This suspension of the bacilli themselves was then diluted with a seven-per-cent. solution of chloride of sodium. They developed the fact that *sensibilisatrice* is present almost constantly in the serum of the phthisical, it was in evidence once in a case of pulmonary tuberculosis before the period of softening, but the tendency seemed to be that it rarely occurred before the patient began to give clinical signs of the disease. They also found it with the aid of bacilli killed by boiling for one hour at a temperature of 72° C. It is true that this is less exact and less regular than when one uses the living germ.

M. MAUREL at the Société de Biologie, July 6, 1901, discussed his theory of the mechanism of the cause of accidental death from cocaine-poisoning. We know the changes in form which the leucocytes undergo in the presence of cocaine. Further, when an injection of concentration, namely, 5 to 10 per cent., is made into the veins of rabbits (excepting the veins of the portal system), death promptly occurs when the dose is .01 centigram per kilogram weight of the animal. This familiar change in the leucocytes is that they assume spheroidal form. On the other hand, by using solutions of less strength, for example, 1-400, he was able to inject up to .03 centigram of cocaine without producing any symptoms whatever, although the amount was also per kilogram of the animal's weight. The injections were all intravenous. By the hypodermatic method a result was obtained, but much less intense. By the arteries a very active effect upon the white blood-cells was seen; but 0.100 gram per kilogram of the animal weight could be used before causing death. A similar effect was seen when the portal venous system was used. It appears then that the danger of cocaine lies in injection into the veins, other than the portal, in a concentration sufficient to either kill the leucocytes or to cause them in large quantities to assume the spheroidal shape. He also found in the pulmonary vessels great accumulations of these white cells forming real embolisms. Hence he concludes that in sudden death from cocaine there exists an embolism of the pulmonary vessels composed of such dead or spheroidal white blood-cells.

SOCIETY PROCEEDINGS.

BRITISH MEDICAL ASSOCIATION.

FIRST DAY—JULY 30, 1901.

(Continued from page 236.)

Address in Medicine.—Dr. James F. Goodhart of London gave an address, entitled "Friends in Council," in which he spoke of the doctor as the potter and the wheel of animal life and their mutual relation to the living body of their patient. In speaking of the vitality of life he said, "All our parts are one. So absolutely one that it is impossible to suffer bad pain in two separate parts of the body at the same time—one comes and the other goes. So absolutely one that when one thinks hard the feet grow cold, so one that when one member of the body suffers all the members suffer with it; so one that the temporary failure to lock or unlock the points at the many junctions and sidings will disarrange the whole. So much so that to any thinker sufficiently detached from himself it may well seem that the harmonics of the song of life are so extremely intricate as to be impossible of performance. And yet the song of life is sung, and on the whole to most of us the result is beautiful. And then behind all, or rather before it, is this curious unfathomable mystery, 'the boon of life.' 'I needs must live,' the body seems to say. Some cynic asks where is the necessity. But that is life, or all we know about it. The 'needs must' live, an unconscious blind unquenchable energy

that carries on the being irrespective of his will, and which, blending with his conscious will, renders the clay at once so plastic, and yet too at one and the same time so unimpressionable."

Vital Energy.—He then went on to speak of the living energy of the body and its influence to keep men alive under diverse conditions. "The spirit of life has no knowledge of death. It is always eager, and death comes to it as a catastrophe by the fault or decay of its subordinate ministers—the brain, the heart, lungs, liver, skin, and so on. And this irrepressible living energy will carry on to old age a very weakly flesh. In saying this I think of the disappointed ones in the race, the tired, the painful; for I have come to the conclusion that there are those who are tired, who are full of pain, from early years even to old age. There are many of these who have missed their mark, who must be very weary of life, but the motive force of their being will not let them go. I suppose, too, that this ever restless, yearning life within us tends to show up the weaknesses of our bodily construction. It is, no doubt, only to be expected that with a restless driving power within us joints that are losing the polish of their early smoothness, bores that no longer allow of sureness of aim, tired bodies that need sleep or rest—organs, in short, that now work with labor that before ran riot in their unconscious ease—should, if stimulated, express their work in weariness that is perhaps worse than pain. Let me give an example: There are a large number of people who at the present day come and tell you that they cannot think or that they cannot concentrate their thoughts. I seldom find that the associates of these have observed any difference in them. They can, in fact, think well enough, only thought is conducted with a sense of labor now, whereas in times gone by it had glided on untold. Who does not know, too, of the common complaint of muscular fatigue, the man or woman who is always tired? The muscular apparatus works with conscious labor, and thus all the pleasure of living is taken away; and you cannot cure these people, because they are mostly people full of vital activity; the spirit within them is a willing one but the flesh is weak."

The Difficulties of Medicine.—"It is clear, without laboring the point, that a body so composite as ours is so very delicate a machine that there must be many and many a case presented to us where we do not, many even where we cannot, know what is the matter, and taking even the most favorable view of the progress of scientific discovery it is probable that this will be so till time shall be no longer. We cannot know because the intricacy of the machine hinders one in getting at the real facts. We cannot know because even when we have got at the facts we cannot be sure that the remedies used will get at the disease. When we come out of the aloofness of the contemplation of growth, nutrition, degeneration, and death to take part in the active grappling with these by stimulating this function and dulling that, in the attempt, in short, to arrest or stop disease, our difficulties become appalling, but this is quite unrecognized by most of those with whom we have to deal. Take the liver or the bones as concrete examples. Of the bones and the exchanges that go on between them and the other component parts of the body, I think we may say we know nothing, and yet no doubt they extract material from the general store that the general store is better without, and they return to the common stock material which is beter adapted by the abstraction for the purposes of other parts. Then the liver, the largest organ in the body; its imports and exports must be enormous, and from the familiar way in which it is spoken of there cannot be a man in the whole world who does not think he knows all about it. But what are the facts? We know something about the physiology of the liver, but this knowledge has been mostly obtained by experimentation on the lower animals, by observations that occasional cases of disease afford us, and by certain inferences that we draw —very much at second hand—from the changes produced by disease in the organ. But all these things, valuable as they are, and without which where we should be I don't know, yet are very far from giving us that real and intimate knowledge of the living organ that we require to enable us to treat its diseases."

Individual Character in Medicine.—"Take next the vital element and its bearing upon the handling of disease. Here again we are often foiled when we would be positive because of the personal equation, as it is called, the individuality of the patient. When Mrs. Smith asked her doctor why it was that a particular pain possessed her, he is said to have replied with ready wit and no less truth, 'Madam, it is because you are Mrs. Smith.' And the lady no doubt thought her doctor a very amusing man, but she had not a glimmer of the great truth that had been administered in such an excellent coating. But, indeed, that 'because you are Mrs. Smith' constitutes one of, if not the most, insuperable of the difficulties of framing any system of precise medicine, and over and over again fattens crass ignorance at the expense of real knowledge. In the practice of medicine you cannot jump the fact that the inflections of your voice are not exactly like those of any one else; and as long as the world lasts, this variability of the living force, this individuality, will prevent the attainment of the popular desire—a cut and dried remedy—not only for every disease—that is no use to Dick when the remedy touches only Tom's variety; no, we want a remedy for every disease, and for every variety of it, as met with in the young and in the old, in the otherwise

healthy and the unhealthy, under the specious garb of mildness, or the pronounced type of malignity, that is another of the cruxes of medicine that the world wots little of. And then as part of the animal energy of man, of the spirit of life, perhaps the chief human expression of it, comes that wonderful indescribable something that we call hope. One hears talk of forlorn hopes, but hope is never forlorn; its springs is always light and buoyant, and it is as indomitable as life itself. Of all the unnatural conditions of which medicine takes count, perhaps none is so much so as life without hope. When hope flies out of the window death is lurking at the door, but in the good providence of God man cannot quench it, and I beseech you that you never try. With human life, then, and hope before us we may pass on to the patient who embodies them, and to the doctor who, while also similarly endowed, has yet to influence and control them as best he may."

Patients.—"We must for a moment consider each of the two parties, their influence upon each other and thus upon the progress or otherwise of scientific medicine. Are we gradually surging on by a natural process of evolution to a perfect system of the treatment of disease? Is the management of the sick man and the ailing man in the present day as perfect as it might be? On the larger side of the subject—that of preventive medicine and the scientific knowledge of disease—it is obvious that great discoveries have been made in the recent past, and the dawn is surely breaking of a still more brilliant day. So far as this side is concerned I think it may be said that we are steadily working upwards to that time when much of the present gross disease—tuberculosis, microbic fevers, etc.—shall be no longer. On looking over the field of disease, although it is said that the average duration of life is longer than it was, I neither find that medicine is less often in request, nor that an ailing public is less in evidence. I am here to contend on the contrary, that we are growing more and more sensitive about our health, more impatient when the flies of ill health worry us, that we are crying more loudly for a cure for every disease, whether it be one that is commencing and curable or so advanced that—as, say, in a bad case of phthisis—the greater part of an organ is practically destroyed, and a restoration of its health impossible. This is shown in several ways: in the first place the sick man wants to know too much. He wants to know what is the matter with him when it is not possible to tell him; moreover, he will have an answer, and if not he thinks the doctor an ignoramus, and calls in someone else. It is because the public will have a disease ticketed when there is no means of identification that these difficulties arise, and because it still sets such store by the man who plunges. How much better would it be if the obvious were better recognized that the doctor is but mortal, and if others than ourselves could take part intelligently in our doubts and difficulties. And having got a name for his complaint, from either wisdom or ignorance, the patient thinks his physic tumbles out of the same slot, and that between the two he will be cured offhand."

Doctors.—"And now for the potter who has more or less to fashion this clay as it somewhat impulsively rolls along under the momentum of the wheel of life. The simile is not a good one, for the doctor is never a fashioner, although sometimes in the plenitude of his pride he conceives himself to be, and then o'erleaps himself, not he, but his patient, unfortunately, falling on the other side. What are we doing in this impatient, restless age to stem the tide, to stay the panic, to bid the people keep its head? I do not mean in the immediate present, for we always do our best for the patient according to our lights, but with our eye on the future and that continuous progress as individuals for which the Goddess of Medicine is marking time, and surely points us to. I do not doubt, I say, that everyone of us does his best for the man that consults him, but I am not sure that in attending to the exigencies of the immediate present we do sufficiently take heed of the future. First may be put a morbid readiness on our part to detect disease. Engaged as we are in this pursuit there comes a risk that we too little appreciate the wide range of health; that is, how good a state of health is compatible with numberless slight and even sometimes considerable departures from normal. We tend to make our standard too severe for practical purposes."

Drugs.—"Now, why do we give drugs? To cure disease, you answer at once, and think the question unnecessary. But wait a minute; we give drugs for several other reasons, some of which are far less free from criticism. For example, drugs are often given, not because the disease demands one, but because the patient is not happy till he gets it: too often he is not happy even then. They are given sometimes to hide our ignorance, I fear, or to mark time while we watch and wait; they are given sometimes as a gambler on the Stock Exchange speculates in 'futures,' an enhanced reputation being the windfall that it is hoped to secure; and then we often give drugs as an experiment in the hope that they may do good. I will deal with this last more especially, for it is a reason for giving drugs about which the public are peculiarly sensitive and ill-informed. It is often said as a matter of prejudice against the hospitals of our country—than which none could possibly be conducted more humanely and considerately—that the patients are made the subjects of experiment. So they are. But this happens not only in the hospital. If it be true—and it is true—that you and I are unique in our way, and that it is this individualism of

man that constitutes the great barrier of the evolution of any system of medication, it follows that each new patient who demands treatment is more or less a case for experiment, and it is by experiment of this qualified kind—upon the king as he sits upon his throne, as for the poorest being within his realm—not only that the value of drugs is established and new powers gained over disease, but by which an increase of knowledge of disease itself is gained. The cure of disease is always the fundamental object; but not far behind it should come the alert eye to watch the deviations from the hypothetic normal which the individual resistance or the drug in its action may show in the course of the case. All treatment by drugs is more or less of an experiment, and it is, indeed, in this fact that the enormous number of new drugs daily poured upon us finds its justification. Many and many an ailment that afflicts mankind badly needs a remedy, but for which, as yet, no remedy is opportune; and who knows but what in each new drug some human ill may find alleviation?"

The Dangers of Routine and Fashion.—"Now all this routine and fashion, and remember I have only taken one or two instances out of numbers that lie at my hand, I object to, and I do so because it all tends to establish false relationships between the doctor and his patient, and let me attempt to show you how. The patient first of all asks us for a name to his disease, and whether we know or not we give him one. In so doing we, as I say, speculate in 'futures'; and this is a form of business that very often ends in bankruptcy. No remark is more frequent at a consultation than that we must give a name to the disease. I object to giving a name to anything I am not sure about, and when a man says to me, 'That is all very well for you, but it would never do for me,' I object still more, because the general practitioner is the great instructor of the public in matters medical. I have not a tithe of the influence that he has, and by giving names to symptoms that are doubtful in their significance, he is first of all losing an opportunity of insisting upon the dignity of ignorance; then he is conveying to the public the erroneous notion that we have the power of insight into problems that are at the time inscrutable; and we ultimately end in deceiving ourselves into thinking that we know much more than we do, an idea that is fatal to the progress of knowledge. There are hundreds of examples that might be given, but the various febrile disorders are the most fertile in discords of this sort. It is often absolutely impossible in the early days of typhoid fever to say what is the matter; equally is it absolutely impossible in many of the eruptive fevers to say what of several things will eventually declare itself. It is not ignorance but knowledge that halts. When I first entered Guy's Hospital, some thirty-six years ago, it was a common saying about one of our staff at that time, and certainly one of the best physicians of that day, that he knew so much that he could but seldom be prevailed upon to give a positive diagnosis. And it is true, as Sir Arthur Helps says in the book from which I have borrowed the title of this address, that knowledge brings doubts and exceptions and limitations that are all hindrances to vigorous statement."

Indiscriminate Drug-Taking.—"Then a word about the evil of letting the public force our hand in the matter of drug-taking. I have already alluded to routine as destructive of all scientific observation, enabling as it does the giver to see only cures and nothing of failures, though they be in very truth staring him in the face. But I am now alluding especially to the numberless occasions when drugs are given, there being at the time no distinct indication for giving anything. There is no doubt that this is a very common and bad fault with us. I do not say it must never be practised. There are times when the sick are not reasonable beings, and unless they have a bottle of medicine to anchor their faith to (oh, shifting sands!) they are in a state of unrest that is positively harmful to their progress. But there are multitudes who are not in this parlous state, who are capable of listening to reason, but who as now, having been taught to look for their prescription or their bottle of medicine, have no idea of the value of advice only, or of the need of the watchful eye. Why, we are all familiar with the 'Are not you going to give me a prescription?' when you have been pouring in advice with much prodigality of tongue, and had flattered yourself that you had gained a disciple; and there is no need to go far to be absolutely sure that the great body of the public, rich and poor, pay for our prescription, and that they do not value by a button any advice that lies outside it."

Value of Advice.—"But I think there is another reason for this indifference to the value of advice which, although it is perhaps one that savors of the sordid, I must nevertheless touch upon. I have often inwardly contrasted the two professions of law and medicine, how in the one advice pure and simple is sought and found, and the givers thereof acquire positions of milk and honey, and find themselves mounting to the high places of the land. In the other medicine passes for the consideration, and, well! the sellers thereof do not seem to possess themselves of many coveted places of honor. And if you ask me why this is, I believe it to be because we make ourselves too cheap. Advice—just think of it! A product of so unique a value, that when a man of great experience in the world of medicine dies his knowledge dies with him; no other man can supply his place, and there is a dead loss to the community of a mine of unrealized information. You all know that very clever signboard in which a bullock is seen gazing yearn-

ingly upon a small jar of meat extract and exclaiming, 'Alas! my brother.' But I often wish that I could pot my brothers as they flit from off the stage; my trouble is that my masters die unbottled. And yet we 'give' advice, and there are those in number who not only accept, but ask the gift. Oh, dreadful degradation that advice, a priceless article, should fall in value below cheese and butter! It is told of the late Sir Andrew Clark, with what truth I do not know, that when he was asked to give gratuitous advice he said, 'No; but I will give you the money with which you can purchase it.' Whoever said this was a wise man; for on the one hand there was in the answer the generosity that knows no bounds of medicine to poverty; there was on the other the dignity and self-respect that fully understood the preciousness of the knowledge that he had the power to impart; and we shall never make the public understand the true position of medicine until we set a higher value upon *ourselves* and upon the *advice* we give. The laborer is worthy of his hire is but one side of the question, and not the best side, for it might be held to cover many a sordid act; the other and much the more important is surely this, 'See to it that the hire is worthy of the laborer.' And although expressed in these terms the face value may seem to be one of low ideals, I am far from thinking, as I speak, of any money consideration, but of the higher and nobler recompense of dignity and self-respect. And it is, in part, because I think that to careful observation it must seem that the very nobleness and generosity of medicine does tend somewhat to make us forget the importance to its well-being of these just rewards that I have chosen this subject for my address to-night."

Section of Medicine.

Research in Medicine and Therapeutics.—Dr. E. T. Wilson of Cheltenham read a paper on this subject. The rapid evolution and general trend of modern medicine are due to the spirit of the times brought about by facilities for communication and interchange of thought. Science is no longer cramped, but has become free to the world. Of the newer problems which are to be presented he mentioned the relationship of peripheral neuritis and beer-drinking and malaria as of special interest at the present meeting of the Association. Activity prevails in every department of medicine and surgery, but in none have so many valuable results been obtained, in none have so many hopes been excited as in the scientific study of the infective diseases, of the exotic fauna and flora of the human body. The bacteriological diagnosis of certain diseases has become a matter of routine, and there can be little doubt that in the near future a need will arise for laboratories and specialists in every large center of population, to whom questions insoluble or doubtful in their clinical aspects may be referred, on whom will rest also the responsibility for the supply of such vaccines and serums as may be required in their several districts.

Improved Diagnosis.—An improved diagnosis, however, is but a small portion of the gain which has been derived from a scientific investigation of the causes of disease. Over a large part of the field of therapeutics a new direction has been given to treatment. Students are learning to look beyond the collection of symptoms which were once held to constitute the disease, with the result that, although symptoms will continue to claim the attention, and certainly that of patients, the true objective of treatment will be the micro-organism itself. Physicians are learning more and more at the hands of a new pathology to regard the human body as a battle ground on which important issues have to be fought out between invading organisms and poisons coming from without, on the one hand, and on the other those forces inherent in the system, of which so little is known as yet, but which may be summed up in the term "resistance," or in one older and better known, the *"vis medicatrix Naturæ."* Every disease which can be won over for the infective class becomes at once, if only in theory, preventable, and our treatment acquires a tangible and definite aim. In the first line of defence comes the destruction of the parasite before it obtains a lodgment in the body; and this will be divided between the health officer and the medical attendant, for it comprises the whole array of hygienic measures, including the isolation of the infected sick.

Parasites, Internal and External.—The means of attacking the parasite within the body are at present limited in extent, but some progress has been made, as, for instance, in the treatment of lupus by sun exposures, of rodent ulcer by the X-ray, and of tuberculosis of the lung by life in the open air. An additional defence is found in the vaccines, by which immunity, artificial or natural, is secured, such as the Cuban enjoys against yellow fever, or the vaccinated with cow-pox against variola. In serumtherapy an appeal is made to powers which cannot at present be explained, whereby for each several toxin produced by an organism in the blood a special antitoxin is forthcoming, and it is the possibility of supplementing this supply by artificial means which has deprived diseases, such as diphtheria and tetanus, of the terror with which they were wont to be regarded. Lastly, behind all these, there are in reserve the enormous powers residing in the blood-cells of offering a successful resistance to the invading organisms, a resistance the vigor of which is easily impaired by unfavorable circumstances, and which it will become more and more the aim of medicine to foster and improve.

Work Still to Be Done.—The number of the infective diseases is by no means complete, and it becomes almost possible to breathe a word of hope where despair has hitherto prevailed, that medicine may yet find work to do in the treatment, preventive it may be, of the neoplasms which occur with ever-increasing frequency. The cancer which the surgeon now removes with such consummate skill is not the disease; it had its beginnings in an insignificant outgrowth, during which the rapidly proliferating cells, estranged from their accustomed environment, would probably be vulnerable were it known how and where to attack them; and further back still lies the exciting cause, on the exact nature of which medical opinion is divided; there seems, however, good ground for suspecting that here, too, one has to deal with a micro-organism, and an infective disease, the remedies for which, though they may be long in coming, cannot be regarded as beyond the reach of human attainment.

Chronic Diseases of Joints.—Dr. A. E. Garrod opened the discussion on this subject. He said that several types should be differentiated, ranging in anatomical appearances, pathological processes and clinical features. Two characteristic varieties of rheumatoid arthritis were a fusiform type, occurring in early life, even in children with much disturbance of health, and a nodular type occurring in more advanced life, with little effect on bodily condition. The former had been considered to have alliances to rheumatism, the latter to gout, but it was by no means certain that such relationship exists. Clinical methods were insufficient to separate the affections.

Cheltenham Waters.—Dr. A. P. Luff said that many patients were sent yearly to Kissingen, Wiesbaden, Carlsbad and other German spas who might better go to Cheltenham. Two varieties of waters were to be found there, one resembling Marienbad waters, rich in chloride and sulphate of sodium; the other contained much magnesium and sodium sulphate. They were useful in constipation, obesity and dyspepsia and not useful in gout, but were valuable in intestinal catarrhs, glycosuria and rheumatoid arthritis. The summer season was most favorable. A wholesome activity on the part of the authorities would bring about a movement in the restoration of this city's old time popularity as a health resort.

Pneumococcus Arthritis.—Dr. Nathan Raw read this paper. He discussed in brief the possibility of metastatic involvement of different regions of the body by the diplococcus of Fraenkel and gave the histories of seven cases in which involvement of the joints had occurred during the course of frank pneumonias and in which the organism was obtained from the affected surfaces.

SECTION OF SURGERY.

Surgical Treatment of Renal Tension.—Dr. Reginal Harrison of London discussed this important topic under three heads: What grounds are there to suppose that increased renal tension may induce kidney lesions? Can such tension be relieved by surgical means? and how? Certain marked analogies of the effects of increased arterial tension on important structures, such as in the eye in glaucoma, etc., render it more than likely that like conditions of tension in the kidneys bring about grave structural changes, and clinical surgical experience in operations on the kidney has led him to believe that such tension does bring about nephritis, and the relief of the tension helps the kidney lesion; it also has its effects upon the general tension of the entire circulatory apparatus which is so markedly altered in kidney lesions. He then discussed in detail the methods devised by him to make an incision in the capsule of the kidney and thus relieve the tension in that organ. (See MEDICAL NEWS, Vol. 78, p. 447.)

Operative Treatment of Renal Calculus.—Dr. J. Hutchinson, Jr., of London said that the use of the X-ray had improved the treatment of this disease in that it had made diagnosis positive, had shown the size, number and location of the foreign bodies, and had made operation simpler, safer and surer. The safety of opening the pelvis of the kidney rendered it unnecesary to split the cortex, and thus made the operation much more simple and less dangerous.

Gastric Dilatation Due to Movable Kidney.—Dr. H. Bramwell of Cheltenham reported a unique case of movable kidney which dragged with it its peritoneal coating, forming thereby thick constricting bands which interfered with the functions of many of the hollow viscera, notably the pylorus. This was constricted and its spasmodic closure gave rise to an enormous distention of the stomach, bringing about the patient's death.

Femoral Hernia.—Dr. R. H. Parry of Glasgow described an operation for closing the crural canal from above. By means of his method the cup-shaped remnant of the crural canal was done away with, and the liability to damage of the femoral vein was avoided. The technic of the operation should be consulted in the original.

Shock in Prolonged Operation.—Dr. W. H. Brown of Leeds spoke of the well-known use of saline transfusion in the treatment of this condition.

SECTION OF OBSTETRICS AND GYNECOLOGY.

Puerperal Fever, Uterine Cancer, and Falling Birth-Rates.—These were the subjects discussed by Dr. J. W. Byers of Belfast in the opening address before this Section. In 1847-1856 the mortality from puerperal fever was in England and Wales 1.8 per 1,000. It rose to 2.28 in 1875-1884, and to 2.46 in 1886-

1895. The following figures give the most recent available statistics:

Year.	Deaths from Puerperal Fever.	Death-rate from Puerperal Fever per 1,000 births.
1895	1,849	2 0
1896	2,053	2.2
1897	1,836	1.9
1898	1,707	1 8
1899	1,908	2.0

Deaths of women at all ages from puerperal fever and other accidents of childbirth per 1,000 registered births in England and Wales: 1871-80, 4.72; 1881-90, 4.73; 1891-99, 5.12.

The following figures show the number of deaths in Ireland tabulated under parturition (accidents) and puerperal fever:

Year.	Total.	Death-rate per 1,000 Births Registered.
1895	769	7.2
1896	679	6.3
1897	696	6.5
1898	560	5.3
1899	601	5.8

For the same years the deaths and rate per 1,000 from puerperal fever for the whole of Ireland were as follows: 1895, 3.0; 1896, 2.3; 1897, 2.1; 1898, 1.7; 1899, 2.0.

TABLE SHOWING THE DEATH-RATE FROM PUERPERAL FEVER IN SCOTLAND DURING THE FIVE YEARS, 1895-1899.

Year.	Number of Deaths.	Proportion in Every 100,000 Female Population.	Proportion in Every 10,000 specified. Causes of Death.
1895	253	12	62
1896	220	9	63
1897	205	9	52
1898	227	10	59
1899	214	10	54

STATISTICS OF THE ROTUNDA HOSPITAL.—One may contrast these lamentable statistics with the following returns for the last two years of the practice of the Rotunda Hospital, the largest lying-in charity in the three Kingdoms:

MORTALITY AT THE ROTUNDA HOSPITAL FOR THE YEARS 1898-99 AND 1899-1900.

——	1898-99.	1899-1900.
Intern Maternity:		
Total cases	1,591	1,560
Total mortality	10	6
Percentage mortality	0.62	0.38
Mortality from sepsis (2 of these admitted septic)	5	0
Extern Maternity:		
Total cases	2,163	2,109
Total mortality	8	5
Percentage mortality	0.36	0.23
Mortality from sepsis	2	0
Total cases	3,754	3,669
Total Percentage	0.47	0.27

For two years the total was 7,423, and the percentage 0.39.

These figures he said should make those who are teachers feel how great is their responsibility, and that all efforts should be redoubled in urging upon students the importance of regarding the process of labor as a natural one, and not to be lightly interfered with unless Nature herself should fail, and that if interference becomes necessary they should use exactly the same antiseptic precautions that they see employed in any gynecological operation. It is by the observation of these two principles—the avoidance of meddlesome interference and by the rigid use of antiseptic principles—that the practitioner may hope that in the present century the occurrence of puerperal fever will eventually be as rare in private practice as it became in the nineteenth century in lying-in hospitals. The importance of early diagnosis of cancer of the uterus was dwelt upon. Any woman, he said, with abnormal hemorrhage at any age, and especially if she is over thirty-five years of age, demands the most careful clinical examination.

The Falling Birth-Rate.—During the present year the public press has been calling special attention to the falling birth-rate. It would appear that in England and Wales in 1861-71 the birth-rate per 1,000 was 34.8. In 1871-81 it was 34.7; in 1891 it was 31.4 per 1,000; and since that it has steadily gone down until in the last year of the century, 1900, it was only 29 per 1,000. In 1875 35 children were born in the United Kingdom for each 1,000 of the population, while in 1900 there were only 29. In other words, this means for our population of 41½ millions we are losing 249,000 children annually, and the birth-rate has fallen by 2.67 in the last ten years. The actual increase of the population of England and Wales is due to the fall in the death-rate and the increase of immigration. We are thus rapidly in England approaching the condition prevailing for some time in France and America. It was not for him at present to discuss the causes of this declining birth-rate; rather his duty was to ask what remedy can doctors suggest to combat a state of matters which, from a national and imperial standpoint, must be regarded as most unsatisfactory. If fewer children are in the future to be born in this country, efforts must be doubled to lower the high death-rate of infants, which during the first year of life amounts in England to 154 per 1,000, by teaching the people to pay much greater attention to rearing their children properly, and by urging the public authorities to provide an adequate supply of pure milk. Our American friends are far ahead in such matters, and they showed their usual extraordinary enterprise last summer, when they sent pure, non-sterilized milk from various parts of the States (Illinois, New Jersey, and New York) to the Paris Exhibition, where it was actually pronounced better than the average milk sold in the grounds. Quite recently "The Rockefeller Institution for Medical Research," founded by a gift of £40,000 from the millionaire whose name it bears, has decided that the first investigations to be undertaken

by the scientific experts connected with it will be to co-operate with the New York Board of Health in studying the milk supply and the contaminated article as a source of danger. But this serious problem may also be attacked in another way by taking greater precautions when a woman is pregnant that she may give birth both to a living and healthy child; in other words, more care must be taken to combat those conditions which are so dangerous to the child's life before and during its birth. It is still too frequently the practice of the present day, when a patient engages a medical man to attend at her confinement, simply to note the engagement, to give a few general directions, or perchance none at all, and perhaps in some cases, to examine the urine. Obstetricians should give a much more careful attention to patients who are pregnant, and especially in the case of those looking forward to their first confinement. A pregnant woman, when she engages a doctor to attend her, should be examined as carefully as if she were an applicant for life insurance; in this way he may at an early date detect a flaw in some of her organs (heart, kidneys, lungs, etc.), the knowledge of which may lead him to adopt a judicious prophylactic treatment. Patients should be instructed on such questions as diet, exercise, and management of the secretions; and a most careful examination should be made of the urine from the fourth month onwards, not merely as to the presence of albumen, but in reference to its total amount and the reduction of urea. In this way a form of toxemia (eclampsia), so fatal to mother and child, may from its early detection be carefully warded off, for it must be admitted that, in the vast majority of cases, the treatment of eclampsia, like postpartum hemorrhage, is its prevention. Toward the end of gestation a most careful abdominal examination should be made, so that the position of the fetus may be learned, the amount of liquor amnii, the presence or not of an abdominal tumor, and, if there is the least suspicion of deformity, the pelvic cavity should be most carefully measured. One must also guard against the dread influence of the syphilitic poison and the injurious effects of anemia. In the case of multiparæ, an accurate history of the previous pregnancies and labors is of the utmost importance. In this way, by a careful and if necessary by a repeated examination of the patient, by an early detection of complications, they may be warded off or kept in such abeyance that their danger is minimized; and, if there should be any deformity of the pelvis, the method of delivery best suited for each particular case may be decided upon. By all these measures one can hope that not only a living but a healthy child may be born, and that by careful management of the patient during and after her confinement no subsequent gynecological disease may ensue which so often gives rise either to a permanent sterility or to an early subsequent miscarriage.

Miscarriage, Prevention and Treatment.—Dr. P. Horrocks of London spoke of the different varieties of damage to the normal attachment between maternal and fetal parts, the fetal pathological conditions and the maternal diseases general or local. The things to be avoided, he said, were active exercises indoors or in the open, falls, blows, coitus, shocks, frights, bad dress, alcohol, hot sitz baths, emotional excitement and late hours. Things to be corrected were obstructions, inflammations, displacements, unsuitable diet, dyspepsia, flatulence and colic. Conditions to be treated were syphilis, fits, bad health, anemia, zymotic diseases, lacerations of cervix, and pyrexia. The lines of treatment were those commonly in use and described in textbooks.

Malignant Decidua.—Dr. Horrocks read notes on a case of this kind and exhibited specimens.

Cæsarian Section.—Dr. M. Munro Kerr of Glasgow said that the operation had been performed in the Glasgow Maternity between sixty and seventy times since April, 1888, that septicemia had been the cause of death in all the fatal cases, and that the infection had come by way of the vagina and cervix rather than by the abdominal wound. Preparatory cleansing of the vagina, therefore, was a prerequisite when this procedure was under consideration. The uterus was not drawn out through the wound; the incision was longitudinal and in the middle line. The patients were rendered sterile by tying the Fallopian tubes in two places and excising between.

SECTION OF TROPICAL DISEASES.

Advance in Knowledge of Tropical Diseases.—Dr. Ronal Ross of Liverpool prepared this paper, taking up in brief the advances made in a number of tropical diseases.

Yellow Fever.—The discovery of at least one mode of infection in yellow fever—a discovery of the highest importance to mankind—emanates from America. For some time past several of our American colleagues, stimulated by recent observations in connection with malaria, have sought an experimental verification of the hypothesis of Finlay and others, that yellow fever also is communicated by the bite of gnats. Insects fed on patients were subsequently induced to bite healthy persons who volunteered for the experiment. The results were negative until the gnats were kept for an interval of twelve or more days between the two operations. Success was now immediate. Drs. Reed, Carroll, and Agramonte record in their last report that out of seven non-immune persons subjected by them to the bites of infected mosquitoes, six yielded undeniably

positive reactions. At the same time, seven non-immunes whom they endeavored to infect by means of the fomites of patients under peculiarly favorable circumstances, remained in every case free from the disease. The experiments were conducted under the most stringently scientific conditions. Although the mosquito theory of yellow fever does not possess the parasitological basis of the mosquito theory of malaria, the differential observations of Reed, Carroll and Agramonte are of a nature to leave no doubt concerning the soundness of their conclusions. Some of the tests have involved great heroism on the part of those who were subjected to them. Since the death of Dr. Jesse W. Lazear we have to deplore that of Dr. Walter Myers, one of our most promising young pathologists, who lost his life from yellow fever when on a deputation from Liverpool to study that disease.

Ankylostoma Duodenale.—Another important advance is contained in the confirmation of Giles's life-history of the ankylostoma duodenale by Annett, details of which will shortly be published. These observations throw a vivid light on the route of infection adopted by these dangerous and widespread parasites.

Undulant Fever.—Owing to observations made by Wright on the serum reaction in undulant (Malta) fever, this disease has been shown to exist in India, Hongkong, the United States, the West Indies, and Brazil—a most important fact in connection with the great subject of tropical fevers.

Malaria.—The recent advance in our knowledge of malaria has been well maintained by numerous observers. The practical side of the mosquito theory, which at once became predominant after the determination of the life-history of the parasites, has been energetically treated by Koch and his assistants, who have successfully dealt with malaria on a large scale by means of quinine. Similar work has been performed with success in the United States, and in Italy. In British possessions isolated efforts to deal with malaria according to the new principles have been made by Sir William MacGregor and Strachan at Lagos, and by Thomson and Young at Hongkong; but the country generally has not adopted an intelligent attitude in this connection. On the other hand, British workers have closely studied details of the malaria question in many parts of the world. We must refer especially to the good work done in Central and West Africa by the Malaria Commission of the Royal Society, and to an admirable sanitary survey of Nigeria made by the Liverpool expedition during the last year. Direct cultivations of the parasites have been reported by Daniels, Ziemann, van der Scheer and van Berkelom, and Woldert in various countries—all in *Anopheles;* while Manson has completed an interesting crucial experiment for the popular demonstration of the theory by infecting healthy persons (T. Manson and Warren) in London by mosquitoes brought from Italy, and by simultaneously preserving others (Sambon and Low) in health in the Campagna in a mosquito-proof house. Nuttall and Shipley, Christophers and Dutton have closely examined the anatomy of gnats. Nuttall, Cobbett, and Strangeways-Pigg have made interesting researches on *Anopheles* in England, in which, by the way, cultivation experiments have hitherto failed. Gosio, Giles, Reinhold, Ruge, Fearnside, Neveu-Lemaire, and others have done useful work on the subject in many directions. It remains, however, a matter for regret that stronger efforts have not been made to determine the reason why individual gnats of an amenable species so often resist infection. Until this difficulty is cleared away negative experiments with *Culex* cannot be entirely convincing.

Filariasis.—In regard to filariasis the discovery of Low and James has been confirmed and amplified by several observers. Manson has suggested the possibility of reducing lymphatic varix by leading a lymphatic duct below the stricture into a neighboring vein.

SECTION OF STATE MEDICINE.

Statistics and Disease.—Dr. S. F. Murphy, President of the Section, read this paper, in which he advocated a closer attention to statistical information, since by such careful scrutiny many important hygienic deductions might be drawn which would prove of service to state medicine.

Sanitary Administration.—Dr. Bond of Gloucester opened a discussion on this topic dealing with local conditions.

Municipal and County Laboratory Work.—Dr. E. C. Steaton of London in his paper said that laboratory work entered more and more into the routine of public health and sanitary departments. In every large town there was a demand for bacteriological examinations for the general practitioners and also for hospital purposes. The sanitary authorities should pay attention first to matters concerning the public health and not to questions of commercial fraud. It was of more importance that the community should be protected from preventable diseases such as tuberculosis, measles, scarlet fever, typhoid, smallpox and malaria than to be told about and guarded against the lesser evils of glucose in candies, pumpkin rinds in strawberry jams and other matters of commercial adulteration in foods which while all too common are not of great moment after all.

Plague and Its Prevention.—Dr. D. S. Davies of Bristol read this paper, which embodied the central ideas of ship detention, killing of all rats, thorough disinfection, and prevention of interchanges between ship rats and shore rats.

(To be continued.)

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, Held Monday, May 20, 1901.

The President, Parker Syms, M.D., in the Chair.

Cancer of Larynx and Esophagus.—Dr. Francis J. Quinlan presented a set of specimens from a case of cancer of the posterior wall of the larynx, involving the esophagus. When the patient first came under observation the symptoms were very slight, but persistent despite treatment. Absolutely nothing could be seen in the laryngoscopic mirror. The course of the malignant neoplasm was entirely latent for a long while and the symptoms produced were very obscure. After a time the affection began to run an acute course and, finally, the tumor made its appearance at a time when the walls of the esophagus were already infiltrated.

Palliative Treatment.—Radical operation seemed out of the question since all of the malignant neoplasm could not be removed. The ligature of the carotid on the affected side was tried with the idea of starving the growth. Dr. Dawbarn ligated and extirpated a section of the carotid, but this failed to afford any measure of relief and after a halt for a short time in the course of the case, the neoplasm continued its invasion. In a certain number of reported cases, ligation of the carotid has under these circumstances done good in delaying the course of the new growth and making the patient much more comfortable.

Perineal Prostatectomy.—Dr. Parker Syms presented the specimen of an enlarged prostate which had been removed by perineal incision, using a special technic and instrumentation which he has devised. The patient was a man sixty-two years of age and for months had suffered from complete retention of urine. He had only succeeded in evacuating his bladder by the constant practice of catheterization. The bladder was very much distended and capable of containing some nineteen ounces of urine. Dr. Syms used his perineal bulb retractor in order to pull the bladder down. The bulb is inserted empty and is then inflated, when it is easy to secure the presentation of the prostate in the wound in the perineum. The operation as thus performed is very safe as the field of operation is in sight and there is constant opportunity for the operator to assure himself of just where he is working. Dr. Syms has used this instrument and method in nineteen cases. All of them have good function except one in which there had been some purulent complications before the prostatectomy was done.

Results of Operation.—Careful examination of the specimen as removed shows that no mucous membrane was cut away with the prostate and that consequently no part of the bladder or urethra was excised. This is an important point in the removal of the prostate, for strictural complications and relapses of the difficulty of urination, besides the danger of sepsis and infection, are liable to follow the removal of mucous membrane. The patient considers himself completely cured. He is able to retain his urine from four to six hours during the day and does not have to get up at night at all.

Prostatectomy Necessary.—Dr. Newman said in discussing Dr. Syms' case that an examination of the specimen shows that nothing but enucleation would have been of assistance in this case. The suprapubic route for the removal of the prostate is easier and more satisfactory than the perineal. Most of the work in the perineum must be done in the dark. The majority of patients are not satisfied to submit to enucleation of the prostate, though this is sometimes the only remedy for their urinary troubles. Practitioners should oftener suggest the removal of the prostate in certain of these cases, and gradually accustom patients to the idea that ultimate removal may be the only method of relieving their symptoms.

Simplified Prostatectomy.—Dr. Goulay said that Dr. Syms' instrument and his technic for the removal of the prostate has greatly simplified the perineal section in these cases. Dr. Goulay has always opposed the suprapubic method of operation for enlarged prostate. It adds to the danger of complications because of adhesions, the possibility of septic infection, the binding of the bladder to the abdominal wall by adhesions, and so forth. Dr. Goulay has seen two of the cases as treated by Dr. Syms and is very well satisfied with the method of treatment and the results.

Better than Bottini's Method.—Dr. Syms said in closing the discussion that this method of perineal removal of the prostate is in his experience better and more satisfactory than Bottini's operation. The tunneling of the prostate by means of the heated knife is liable to make an incomplete operation and is much less safe than the direct removal of the prostate by his method. After perineal prostectomy there is no temperature, no complication, no shock, and good drainage is provided. The mortality of the operation in reasonably expert hands is practically *nil.* The morbidity is very slight, the relief afforded is complete, and lasting. So far there has been no recurrence of symptoms.

Vaginal Route in Pelvic Disease.—Dr. J. Riddle Goffe said that all forms of gynecological work in surgery can be done by the vaginal route. Even surgical operations for cancer may well be performed in this way. At the present time and until surgical minds are made up as to what the result of complete clearing out of the pelvis in these cases will ultimately bring with it, the only operation that is indicated for cancer of the uterus is vaginal hysterectomy.

Even cysts of the ovary may be tapped and then the ovarian tissues drawn down and removed. Abscesses may be tapped and then all infected tissues removed much more safely and with much less danger of producing peritoneal infection than by the abdominal route.

Advantage of Vaginal Route.—One of the special advantages of operating by the vaginal route is the avoidance of all danger of hernia in the operation wound after the patient's recovery. No matter how carefully operations are done, no matter how expert the surgeon, a certain proportion of patients in whom an abdominal incision has been made will develop hernia. Besides this the scar in the abdominal wall is unsightly and in unmarried women particularly very undesirable. The operation on the vagina leaves absolutely no trace and a hernia has never been known to occur. It is practically impossible. After the operation the patient can go home at the end of the fourth week and perhaps even at the end of the third week. There is no need to wear an abdominal binder for months afterward, nor to wear a support for a long time.

Vaginal Fibroid Operations.—Most cases of fibroids can be operated on through the vagina. Whenever the tumor is confined to the true pelvis this is the route of election. If the tumor is large enough to go beyond the limits of the true pelvis, then operation through the vagina is too slow and difficult. It is not so much the patient as the surgeon who must be spared the labor of cutting up and removing so large a tumor.

Dermoidectomy Per Vaginum.—It is sometimes thought that dermoids should be operated on preferably by the abdominal route. Dermoid cysts may be punctured, however, a certain amount of their fluid contents evacuated, and then the tumors brought down for easy removal by the vaginal route. Dr. Goffe has removed even large tumors in this way with perfect satisfaction and without danger to the patient.

Low Mortality.—The most important features of operations *per vaginam* is the fact that the mortality of the procedure is in reasonably skilled hands practically *nil*. Drainage is always good, the danger of septic infection of the peritoneal cavity is very little and Nature is given a most favorable opportunity to throw off any septic material that may have gained entrance to hitherto uninfected tissues.

Double Salpingectomy.—Dr. William R. Pryor said that gonorrhea, it must be remembered, travels by continuity of tissue and not through the lymph-spaces, as does septic material. Consequently, if an abscess occurs in the tube on one side there is every reason to suspect the presence of infective material in the tube on the other side. The infection has come from the fundus of the uterus and very probably both tubes have been involved. If there is the slightest suspicious appearance in the other tube, it should be removed.

Complications Requiring Abdominal Operation.—In certain cases the abdominal rather than the vaginal route for operation must be chosen. When there are appendiceal complications for instance, the abdominal route is preferable because it is difficult to clear out an appendiceal abscess through the vagina. When gangrene of the colon has occurred as the result of purulent conditions, usually appendiceal in origin, then the abdominal route is better. In 189 cases under Dr. Pryor's treatment, during the last few years, 83 per cent. proved operable through the vagina. There remain a certain number of cases that cannot be operated by the vaginal method. We have learned in recent years that retroflexion of the uterus, especially where the vagina has become shortened as the result of the downward malposition of the uterus, should be let alone. No good is ever accomplished by the operation.

Technic of Vaginal Incision.—The incision for vaginal operative gynecology may be made through the anterior or the posterior fornix. The incision in Douglas's pouch gives better drainage while the patient is lying down and is the preferable method for most operators. There are men of large experience, however, who prefer to make their section between the uterus and the bladder.

Fibroidectomy.—As a general rule, it seems best not to operate upon fibroids except by complete extirpation of the uterus. The growth of fibroids seems to be due to a fibrosis or tendency to fibrotic growths. This is a sort of diathesis and though several tumors are removed, others may remain, the irritation of operation may cause them to increase in size and they will give symptoms which will compel removal later. If the tumor alone is removed the woman should always be warned of the danger of recurrent symptoms because of the growth of other fibroid tumors.

Etiology.—The growth of fibroid tumors occurs from embryonic foci, that is, from material included within the uterine walls that has never reached the full development destined for it during its embryonic period. These fibroid foci are awakened into activity by increased blood-supply to the uterus, or by some irritant that causes special developmental reaction in the tissues. Their growth is provoked therefore by pregnancy, or sepsis, or trauma. As a rule, then, uteri containing fibromata should either be let alone or radical hysterectomy should be done.

Anterior Dermoidectomy.—Owing to the position of the genital organs during the formation of the uterus and ovaries, dermoids usually occur anterior to the uterus. They are better reached, therefore, by an incision through the anterior cul-de-sac followed by stripping the vagina from the bladder. There is usually no difficulty in removing them through the vagina and plenty of room for this purpose can always be secured.

Ectopic Gestation and the Vaginal Route.—It used to be the custom to wait for pathognomonic symptoms in cases of ectopic gestation before suggesting operation. This often involves

serious danger for the patient. By the vaginal method an incision can be made that will at once decide how serious is the condition that is present. If the condition is found to be really one of extra-uterine pregnancy it can be cleaned out and the tissues left to take care of themselves. Parenchymatous oozing can be stopped by pressure, larger vessels can be caught and ligated and the operation can be rapidly completed. This is a very safe method of operating under all circumstances. In general the vaginal route has many advantages and very few disadvantages. It furnishes good drainage, decreases the risk for the patient, absolutely precludes all possibility of hernia and it leaves no ugly incision wound.

Vaginal Route Not New.—Dr. Brothers said that the vaginal route for gynecological surgery was suggested a good many years ago. Dr. T. Gaillard Thomas of New York did some vaginal work, but gave it up because of the technical difficulties involved. Gynecology through the vagina is not an easy proposition. It owes its present popularity to the work of Mackenrodt in Berlin who used it originally for vaginal fixation of the uterus. It is scarcely fair to take an estimate of the value of the vaginal route in gynecology from a surgeon who does most of his work by the vagina, nor, on the other hand, from one who does most of his by the abdominal incision. There are many conditions that may require either one of these methods of operation and their suitability can be best determined by a surgeon who does not confine himself to either form.

Experience in Both Methods.—Dr. Brothers has had an experience of about one hundred operations by each route. There are many advantages attached to vaginal operation, but it requires special expertness. It is not so easy as operation by the abdominal route, because of the limited field of operation. By the abdominal method blood-vessels are under the eye and give no cause for disquietude. In the vagina oozing occurs, especially in certain patients, and the free bleeding makes nice operating extremely difficult. There is no question that the vaginal route is less dangerous. Dr. Brothers' mortality has been *nil*, but this is not true of all vaginal operators. Dr. Brothers knows of two recent deaths.

Indications for Abdominal Operation.—Pus tubes, because of the presence of abdominal adhesions, should always be operated on through an abdominal incision. In these cases the adherent intestines are apt to make the ovarian region not easily accessible. If there are appendicular complications the abdominal route should be chosen. Dr. Brothers has operated upon 85 cases of pus tubes, 25 of them *per vagina*. He employs the latter method of operating less, however, as his experience increases. The practitioner should not require the surgeon to do a vaginal operation, unless the surgeon's own judgment and his expertness in this method of operating make him adopt it for himself in any particular case.

Spread of Gonorrheal Infection.—Dr. Delphey said that there is undoubtedly more shock in operations through the abdomen than through the vagina. For this reason, if no other, the vaginal route should be chosen whenever possible. Surgeons who operate should consult not their own ease, but the safety of the patient. With regard to the spread of gonorrheal infection, the occurrence of buboes shows that the gonococcus may spread through the lymph as well as by continuity. It is true that most cases of so-called gonorrheal buboes are really examples of secondary infection, but in a certain number of cases pure cultures of the gonococci were found in the pus from these inguinal lesions.

Presence of Adhesions.—In closing the discussion Dr. Goffe said that the presence of adhesions is not an indication for operation through the abdomen. As a rule, it is much easier to break up adhesions from below. In order to free organs it is usually necessary to get beneath the mass in order to lift it up. It is much easier to do this from the vagina. The lines of cleavage are not here so hard to find. Undoubtedly operation *per vaginam* requires special experience. This experience is not, however, so highly specialized as is sometimes said. Then the only reason for the specialist is the possibility of greater conservatism. Any general surgeon can remove diseased tissues. It requires the special experience of the gynecologist to decide how much shall be removed and how much can with safety be allowed to remain.

Abdominal Gunshot Wounds.—Dr. Henry Roth read a paper on penetrating gunshot wounds of the abdomen without injury to the abdominal contents. It is an established fact that penetrating wounds of the abdomen may occur without any injury of the intestines or other viscera. Malgaigne doubted this. Larrey was sure that he had seen one case. During the Civil War nine such cases occurred and Stimson has reported some cases. In one of Stimson's cases the wound was made three inches to the left of the umbilicus; only a small amount of blood excluded, no inflammatory reaction occurred, and the patient made an uneventful recovery. In another case the wound was made one inch below and to the left of the umbilicus and the bullet from a 32-caliber revolver was extracted from the muscles of the back at a point about three to four inches above the iliac crest. In a third case the wound was made by a 44-caliber revolver. It was in the right hypochondrium; an abdominal section was made, but no serious visceral penetration was found. The bullet had passed so close to the intestine as to wound the serous and muscular coat, but it had not perforated the bowel, the mucous membrane remaining intact.

Dr. Roth's Case.—The patient wounded himself with a 22-caliber revolver. The bullet passed through his hand before entering his abdomen. This made it very difficult to decide the direction which the bullet took, and no traces of it could be found. After the shot the patient vomited some, but there was very little pain.

There was slight bleeding and the family physician thought it advisable to probe for the bullet. He failed, however, to find any trace of it. After twenty-four hours as the patient was still restless, it was deemed advisable to send him to the hospital. On admission his temperature was 100.6° F., his pulse was about 110; his urine was normal. There was no constipation nor tympanites, and there had been no bleeding since shortly after the infliction of the wound.

Track of the Bullet.—The wound in the abdomen was situated below and one inch to the right of the umbilicus. There was slight tenderness in the neighborhood of the wound, but none over the rest of the abdomen and there was no distention. A director introduced into the bullet wound seemed to show that the bullet had passed downward. It was deemed safer under the circumstances to do a laparotomy. When an abdominal incision was made it was found that the director had made a false passage. The track of the bullet could be followed very closely by the discoloration produced by its passage. The peritoneum was wounded slightly, but direct evidence of penetration could not be found and the abdominal cavity seemed to have been opened by the probe. No wound of the omentum was found, no injury of the spleen had occurred, as could easily be determined, for there had been little intraperitoneal bleeding. There was some hemorrhagic effusion into the peritoneum, but there were no evidences of peritonitis nor of any infection of the peritoneal cavity by intestinal contents.

Treatment and Result.—The abdominal cavity was washed out with a large amount of hot saline solution and then closed. The patient made an absolutely uneventful recovery, all temperature and restlessness disappearing shortly after the closure of the abdominal incision. About two weeks after his admission to the hospital he was about to go out when a final examination disclosed the location of the bullet. It was found in the abdominal wall of the opposite side imbedded in the abdominal muscles. It had not penetrated the abdominal cavity, but had only wandered between the layers covering the abdomen. It was removed under local anesthesia.

Practical Conclusions.—In military surgery there is neither the time nor, as a rule, the proper aseptic precaution needed for prompt operation upon the abdomen. Therefore the practical rule followed in military surgery of treating wounds of the abdomen expectantly seems a good one. In civil life, however, it seems more advisable to open the abdomen, follow the bullet and determine what injuries have been inflicted. Usually some injury of the abdominal viscera will be found, and laparotomy is therefore called for as soon as the patient rallies from the primary shock. Valuable aid will be given the surgeon by the discoloration produced by the bullet. Aseptic laparotomy adds very little to the danger—in fact, it can scarcely be said to add materially to the patient's risk. In the great majority of cases, however, prompt interference will be needed and will save life. A surgeon should not delay for conclusive symptoms of peritoneal involvement, for this always implies a serious risk to the patient, and it will often be impossible to save life under these circumstances.

Wound of Mesentery.—In discussing Dr. Roth's paper, Dr. Goulay said that he has found an encysted bullet in the mesentery of a subject in the dissecting-room in a case in which there had been no injury of the intestines. The wound of entrance into the abdomen had been directly in front, so that somehow the bullet succeeded in finding its way between the coils of intestine. Of course, other such cases have been reported.

Danger of Probing.—Dr. Gallant said that Dr. Roth's case emphasized very clearly indeed the necessity for letting gunshot wounds alone. They should not be probed. If treated as a superficial wound by aseptic sealing, it will heal promptly. He has never seen a gunshot wound suppurate that had not been probed. Especially abdominal wounds must not be probed. If anything is to be done, free incision should be made, but no attempt should be made to follow the track of the bullet with a probe.

THERAPEUTIC HINTS.

The Nasopharynx in Scarlatina.—A grave danger to scarlatina patients is the invasion of the nose by streptococci and their associates. The visible pharynx is disinfected every hour with

℞ Tinct. iodi. ..... 2.0 (ʒss)
Potass. iodid. ..... 1.0 (ɱxv)
Ac. carbol. ..... 0.7 (ɱx)
Aq. q. s. ad. .....120.0 (ʒiv)

This may safely be given in teaspoonful doses to a one-year-old child for several days. The infiltrated mucosa should be irrigated with 1- to 5-per-cent. ichthyol solution every six hours. When the pharyngeal obstruction will not allow of efficient irrigation, a 50-per-cent. alcoholic solution of resorcin, introduced on each side of the uvula, will often be sufficient to open the passage and permit of easier breathing and proper irrigation.—A. Siebert in *Archives of Pediatrics,* Aug., 1901.

Impetigo Contagiosa.—Scrub the affected part with warm water and soap, and cover with five-per-cent. carbolized vaseline, or five-per-cent. carbolic zinc ointment, or half strength ointment of ammoniate of mercury. If many crusts, remove by soaking with hot oil or water before applying the ointment. In the bullous form prick the bullæ at their most dependent part to let the fluid escape.—G. T. Jackson in "Diseases of the Skin."

Umbilical Hemorrhage in Babies.—The arterial power being greatest in the abdominal cavity and near the umbilical ring, the cord must not be cut near the body. Two ligatures are a fair preventive of hemorrhage. Tight bandages

should be avoided. If the cord is cut too short or torn off, and the vessels cannot be secured and tied, two harelip needles may be run through the abdominal wall, and a strong ligature tied beneath them. Moderate compression of the wound, which has been covered with iodoform or salicylic-acid and starch powder and borated cotton by means of a bandage, will serve well. In hemophilia, plaster of Paris has sometimes proved successful and also the actual cautery. Ligation by a running suture is often useless, on account of bleeding from the stitch-channels.—A. JACOBI in "Therapeutics of Infancy and Childhood."

Influenza.—For the influenza as such there is no treatment. The headache, if dependent on inflammation of the frontal sinuses, can be relieved by local application to the nose. For the general headache and pains, phenacetin, in doses of gm. 0.3 (gr. v) every two hours, is the most reliable drug; of less efficacy are antifebrin, antipyrin, morphine and the bromides. The inflammations of the pharynx and tonsils may be alleviated by the local application of cocaine and the internal use of aconite and sodium salicylate. For the bronchitis and pneumonia we employ the ordinary methods of treatment, except when there is a disposition to general venous congestion and failure of the heart's action. In these cases attention to the condition of the circulation is of the greatest consequence. Good results may be obtained by digitalin, mg. ⅛ (gr. $^1/_{500}$), aconitine, mg. ⅙ (gr. $^1/_{375}$), and whisky. For the gastritis we employ small doses of morphine, cocaine, gm. 0.006 (gr. $^1/_{10}$), or sulfonal, gm. 0.2 (gr. iv), mixed with milk. No matter how irritable the stomach may be, I do not believe it wise to let the patients go for many days without feeding them by the mouth. Feeding by rectum amounts to very little for these patients. Colitis is to be treated by rest in bed, restricted diet, and a little opium.—FRANCIS DELAFIELD.

Melena Neonatorum.—The quantity of blood evacuated from the bowels is sometimes enormous, particularly as the blood of the newborn constitutes only five per cent. of the baby's weight. The cases complicated with vomiting are the worst, and are found to have stomach or duodenal ulcers. Competent respiration and an aseptic umbilical wound are the best preventives. The treatment consists of tincture of chloride of iron in drop doses, ice to epigastrium, warmth to limbs, and the administration of food at a low temperature.—A JACOBI in "Therapeutics of Infancy and Childhood."

Erythema Exudativum Multiforme.—Villemin maintains that iodide of potassium, at least gm. 2.0 (gr. xxx) a day, is almost a specific and will abort relapses. Quinine, gm. 1.0-2.0 (gr. xv-xxx), and sodium salicylate, gm. 3.0-4.0 (gr. xlv-lx), a day sometimes abort or check the disease. Arsenic may be tried in chronic cases. The treatment is mainly symptomatic, and directed to relieving constipation, regulating diet, aiding digestion, ameliorating rheumatism or toning up the system. In obstinate cases the patient should be put to bed. Locally, any alkaline solution will afford relief such as

℞ Pulv. calamin. prep. ... 3.0 (gr. xlv)
Zinci oxid. ..... 2.0 (gr. xxx)
Liq. calcis ad. ..... 60.0 (℥ii)

Or liquor plumbi subacetatis diultus, or lead-and-opium wash. Sometimes a simple dusting-powder will do. In erythema nodosum rest in bed is essential and salicylates are especially indicated. —G. T. JACKSON in "Diseases of the Skin."

Etiology of Whooping-Cough.—In expectorations taken from a large number of cases of whooping-cough G. JOCHMANN (*Ctblt. f. Bäk.*, July 12, 1901) has found small, influenza-like bacilli which can be divided into separate classes by their relation to Gram's stain. In this way he accounts for the divided views of observers in regard to the biological properties of the rods seen in this kind of sputum. He thinks that the bacillus found by Czaplewski and Hensel is not the cause of pertussis, as he only found it in four cases and, moreover, it cannot be cultivated on blood-agar. In eighteen cases of pertussis he has isolated a bacillus which grows exclusively on culture media containing hemoglobine.

FURTHER NOTES UPON THE DIAGNOSTIC TEST OF TUBERCULIN.[1]

BY EDWARD O. OTIS, M.D.,
OF BOSTON.

AT the meeting of this Association in 1899 I presented a series of tuberculin tests, published in the Transactions of that year. I have now to present sixty-two additional tests undertaken with two objects in view, namely, (1) to determine how many cases of known syphilis react to tuberculin, and (2) to determine how reliable the test is in suspected or incipient tuberculosis both of the lungs and of other organs or portions of the body. The tuberculin used was Koch's original, imported and diluted as used to a one-per-cent. solution, one-tenth of a cubic centimeter of which solution being one milligram of the original product. The patients were those of an ambulatory clinic, but from former experience I have learned that results so obtained are reliable, and such also was the experience of Dr. R. C. Cabot, who pursued a similar course in his series of tests referred to in my previous paper.[2] Fränkel has also recently declared that the test could be satisfactorily made under these circumstances.

In none of the cases herewith reported were there any serious or alarming symptoms as a result of the injection, so that I am still further confirmed in my opinion previously expressed, that no injurious results follow the diagnostic test of tuberculin in doses up to ten milligrams. There was invariably a little soreness complained of at the point of injection for one or two days following. In most cases the general reaction only was depended upon, but I am inclined to think that there are some few cases of tuberculosis which, for some reason or other, do not give any general reaction, but do give a marked and definite local one, as in No. 4. The dose was two, five, seven, or ten milligrams, never over ten. All the cases were practically afebrile at the time of the injection.

TUBERCULIN TEST IN SYPHILIS. TABLE I.

No.	Condition and Stage.	Sex.	Age.	Temp.	Pulse.	Dose. in mg's.	Result.	Temp. at reactive epoch.

[1] Read before the American Climatological Association, at Niagara Falls, May 30, 1901.

[2] "Polikliniken für Lungenkranke," Zeitschrift für Tuberkulose und Heilstättenwesen, April, 1901.

If from six to twenty-four hours after the injection there was a rise of temperature and the patient complained of marked weakness, sensations of heat and cold, nausea or anorexia, pain in the back and limbs, headache, sweating, either sleeplessness or somnolence, a general "miserable" feeling, a reaction was considered to have taken place. I do not think that any special temperature can in itself be relied upon without some or all of these other symptoms. Sometimes a slight rise of temperature was accompanied by marked constitutional disturbance. Each patient was given a thermometer to take home and requested to hold it under the tongue for five minutes at six o'clock at night, upon going to bed and in the morning on getting up, and then to report the following forenoon. In this way the maximum temperature was obtained at whichever of these three periods it occurred. As the class of patients were more or less ignorant, no attempt was made to teach them how to read the thermometer, the plan just stated was considered a surer, as it was a simpler, one.

The diagnosis of syphilis was carefully made by Dr. C. M. Smith of the Skin and Syphilis Department of the Boston Dispensary, and I desire here to express my thanks to him for so kindly furnishing me with the material for these tests.

First, I present thirty-six cases of the tuberculin test in syphilis or, throwing out No. 11, the only doubtful case, thirty-five. The smallest amount of tuberculin used was two milligrams, the largest ten milligrams. There were six undoubted reactions and five what I have called abortive reactions, in which there were temporary symptoms of a reactive nature, but which I do not think could be called genuine reactions. Considering only the six undoubted reactions we have 17 per cent. of reactions; including the abortive cases, we have 31 per cent.

In the discussion upon Dr. J. M. Anders' paper upon "The Value of the Tuberculin Test in the Diagnosis of Pulmonary Tuberculosis," presented to this Association last year, Dr. Baldwin quoted Beck as showing in his experiments that about one-half the cases of syphilis in which he used the injections reacted to tuberculin. My cases give a much smaller number, only about one-sixth or at most less than one-third. From my experience I cannot think that, however large the number of cases experimented upon, as large a proportion as one-half, or anything near that number, would react. Still, in using the tuberculin test we must always bear in mind the fact that syphilis at whatever stage does give a reaction. Further, there does not seem to be any guide in the activity or quiescence of the syphilitic infection, as to whether or not a reaction is likely to occur. In the most violent reaction I had, in which the temperature went up to 104° F., the case was one of many years' duration and with no active manifestations.

TUBERCULIN TEST IN SUSPECTED OR PROVED TUBERCULOSIS. TABLE II.

No.	Condition.	Sex.	Age.	Temp.	Pulse.	Dose in mg's.	Result.	Temp. at reactive epoch.
1	Suspected tuberculosis of urinary passages	M.	40	99.	74	5	No reaction	98.4
2	Suppurating cervical glands, both sides; dulness over left apex	F.	20	99.5	112	2	Reaction	103.
3	Cough, slight dulness in right back	F.	23	99.8	100	2	No reaction	97.
4	Dulness above and below left clavicle; moist râles; t. b. in sputum	M.	52	99.4	100	2, 5, 8	No general reaction. Marked local reaction with 8 mg.	99.8
5	Dulness over right apex, bronchial resp.; few moist râles on cough	M.	39	99.2	68	5, 8	No reaction	96.
6	Suspected renal tuberculosis	M.	19	98.4	64	5	" "	98.4
7	Fine moist râles below left clavicle; diminished resonance, prolonged exp.; t. b. in sputum	F.	38	98.6	81	7	" "	99.6
8	Dulness left axilla, few moist râles on deep inspiration	M.	28	97.8	62	10	" "	99.6
9	Suspected renal tuberculosis	M.	36	98.8	80	5	" "	99.5
10	Moist râles at both apices	M.	30	98.8	70	8	General and local reaction	101.3
11	Suspected tuberculosis of wrist	F.	40	98.6	74	5	No reaction	98.4
12	Suspected tubercular laryngitis	F.	23	100.	99	5	" "	99.8
13	Lupus of face	F.	29	99.	114	5	General and local reaction	101.2
14	Suspected tuberculosis of anus	M.	50	98.8	80	5	No reaction	98.4
15	Dulness at right apex	M.	42	98.4	80	10	" "	98.4
16	Suspected tubercular epididymitis	M.	30	99.5	90	10	" "	
17	General tuberculous condition; few fine moist râles above spine of scapular in left lung. General evidence of tuberculosis; a few dry râles	M.	41	100.2	100	5	Reaction	102.1
18	below left clavicle; harsh respiration	M.	39	99.6	105	7	"	101.2
19	Suspected tuberculosis of finger and hand	M.	3	99.8	110	1	No reaction	98.
20	Dulness above and below left clavicle; fine râles after cough; harsh respiration	M.		98.3	72	7	" "	97.1
21	Syphilis or tuberculous laryngitis	F.	16	99.1	104	2	Reaction	100.2
22	Suspected tuberculous laryngitis	M.	56	97.5	72	5, 10	Abortive general reaction, local reaction	98.
23	Suspected tuberculosis of septum of nose	F.	40	97.7	88	5	General and local reaction	101.7
24	Few fine moist râles at left apex	M.	52	98.7	90	10	Reaction	103.
25	Dulness over both apices, moist râles, consolidation on right side; t. b. in sputum; fistula in ano.	F.	22	99.2	112	5, 10	No reaction	98.6
26	Possible tuberculous infection at the right apex	M.	39	98.2	72	10	" "	98.

Second, I have twenty-six cases of suspected or proved tuberculosis which give some interesting and perplexing results. Taking the eight cases in which the physical examination showed sufficient evidence of tuberculosis or in which tubercle bacilli were found in the sputum, we have four reactions and four failures to react. In the three cases in which tubercle bacilli were found in the sputum, two did not react; in one 7 milligrams were used, and in the other 5 and 10 milligrams. In the third case in which 2, 5, and 8 milligrams of tuberculin were successively used, only a local reaction was obtained. I have no explanation to offer for these unexpected and disappointing results. Of the remaining eighteen cases of suspected tuberculosis, there were six reactions and twelve failures to react. In no one of those cases which failed to react could tuberculosis be more than suspected, with greater or less probability, by the physical examination. The case of lupus of the face besides giving a general reaction showed a very pretty local one. In a case of chronic laryngitis in which either syphilis or tuberculosis might have been the cause, a reaction was obtained, thus leaving the origin doubtful as before. In using the tuberculin test for suspected tuberculosis, experience would teach us to look carefully for syphilis.

"One swallow does not make a summer," nor should one be discouraged by a few failures, yet I must confess that when a case of tuberculosis not far beyond the incipient stage, with tubercle bacilli in the sputum, fails to react, one's confidence in the test is temporarily at least a little shaken, but it is well to bear in mind that in all such investigations as the above there is always a chance of error, and as yet we do not know what the minimum efficient dose is, and not unlikely it may vary for each individual. One thing I feel sure of—that up to ten milligrams, there is no injurious result to be feared.

A STUDY OF BURNS, WITH A PLEA FOR THEIR MORE RATIONAL TREATMENT.

BY FREDERIC GRIFFITH, M.D.,

OF NEW YORK;

SURGEON, BELLEVUE DISPENSARY; FELLOW OF THE NEW YORK ACADEMY OF MEDICINE.

THIS article is written to arouse interest in a class of surgical injuries which the writer believes are neglected.

The reaction of the body to high degrees of heat in the form of flame or molten metal, boiling fluid, escharotics or electricity, resulting in injuries varying in severity, is the cause of their desultory treatment.

Burns and scalds are the commonest injuries of the body and Holmes ranks them as the most commonly fatal; Cheever of Harvard state that more than three-fourths of all burns occur in children; this I consider too sweeping a statement, although that of one-third to one-half of all deaths given as occurring in the young may well be accepted: A burned child has less vitality to combat such injuries than a grown person and will, therefore, more often succumb.

Of predisposing causes winter months and occupations are foremost in importance. Workers in rolling-mills, blast-furnaces, oil-refineries and coal mines are particularly exposed. In the south, where sugar boiling is carried on extensively and in the turpentine camps many burns result. In large cities where steam laundries are common a peculiarly distressing form of burn occurs. The ironing machine consists of two rolls superimposed; the upper one cold the lower one hot. A common accident is for the "feeder's" fingers to be drawn between the revolving rollers resulting in a crush and a burn of the hand; the burned area being always upon the flexor surfaces of the fingers and palm.

In the arts and trades where escharotic acids and alkalies are used many burns result which are notable for tenacious eschar formation. Electricity, finally, must be added as a common source of burned wounds. They are characterized by death and instantaneous formation due to the intensity of the heat. The wounds present a clean-cut edge, with no redness, and become covered with a brownish eschar; owing to the depth, healing is slow and the scars left are very plain. Hutchinson reports a case in which a very severe electric burn occurred in an individual of such rapid formation that the clothing was not scorched. In this connection so-called burns following X-ray examinations may be mentioned. Prof. Roentgen's dogma that the X-ray is non-calorific has not been disproven.[1] Any case of burn which has resulted from the use of this latest and greatest appliance of electricity to medical science has been due to the heavy electric currents employed in the generation of the X-ray and not to the X-ray itself.

Burns of the throat and nasopharynx are common and always of serious import. Scalding from hot vapors or fluids, when severe cause rapid edema of the mouth, nasopharynx and the larynx as low down as the vocal cords, followed by a gradually increasing dyspnea, until asphyxiation causes death. Cases which are stated to have died from inhalation of flame have really been asphyxiated by smoke, noxious gases of combustion or mechanically suffocated by direct action of the flame. The presence of carbonaceous matter in the mucus contained in the larynx and trachea proves the inhalation of smoke. In such cases the blood is found of a bright red color, as are all the viscera, with large quantities of bloody fluid sometimes found in the arachnoid spaces, death having been caused by carbon-diox-

[1] Recently William Roelins sought to show that the X-ray does produce heat effects. A strong male guinea-pig, placed in a grounded Faraday chamber and exposed to the X-ray two hours daily, died upon the eleventh day of the experiment. A second guinea-pig died on the eighth day after a like exposure. In neither instance were external burns found. From the results of these two experiments Rollins considers that there is an ever-present danger in the use of the X-ray. He advises the physicians to wear glasses of the most non-radiable material that is transparent when using the flouroscope. For the better protection of the patient he would have the X-ray tube covered by non-radiable box from which no X-rays escape, excepting the cone of rays which covers the area to be examined or photographed. The patient should be covered by similar material excepting only the necessary area for examination.

ide poisoning. When in addition the blood is found fluid, high heat has been present. The quickness with which death comes after burns of these parts is well shown by the history of a case reported by Dr. Cleaves of a strong young man who inhaled powdered lime. The symptoms began with coughing and violent pain coming on almost immediately and requiring opiates to subdue. The throat and mouth became edematous, congestion of both lungs took place, moist râles being heard all over the chest. Diarrhea and delirium, with a temperature of 104.5° F., came on with death at the end of 48 hours. Dr. Cleaves thought that the lung congestion was due to a progressive inflammation beginning in the throat, lime particles not entering the bronchi.

E. Schmidt in his report of a case shows the rapidity of action of a scald of these parts in a child, aged three years, who tried to drink from a long-spouted, boiling tea-kettle. The child died next day from paralysis of the heart, following a left-sided pneumonia. Upon postmortem examination the mouth and pharynx were found normal, due to the length of the spout, compelling the child to throw his head back for suction. The entrance of the steam or boiling fluid caused an attempt to scream which demanded a deep inspiration of air and the hot fluid. The epiglottis was thickened and the mucous membrane covering it necrotic. Upon the ridge of the larynx where it joined the esophagus a cresentic necrosed area was found.

According to Dr. Posey lime burns are the most common and the most severe of burns of the eye. The danger lies in the quick chemical change which takes place, accompanied by high heat.

Burns about the mouth, eyelids and the neck are important from the amount of deformity which occurs due to the contraction of the healing wounds. Where the eyelids especially are involved in the cicatricial tissue, eversion or drawing of the lids and displacement of the lacrimal canaliculi occur. This allows the tears to run down over the cheeks because of a continuous conjunctival inflammation due to dust particles which find an easy entrance to the sac. When the mouth is drawn, constant dribbling of saliva and impediment to speech follow as a consequence. Hot liquids, alkalies, and acids swallowed commonly result in esophageal constriction, with accompanying contractions of the stomach if disintegration of that organ does not at once occur as a result of the direct action of the heat agent.

Burns occurring over the large joints, serous cavities or the bladder, are especially capable of producing great internal reaction as the internal organs must take on the extra work of the destroyed skin. Serous inflammation is more common than mucous inflammation after burns and Heath points out that a burn over the front of the body is more serious than one over the back. The extent of area is also more important than the depth of the injury; Druitt observes that extensive burns even of small severity are always dangerous. A burn over the belly is often followed by peritonitis or enteritis; Dr. Smith has reported the case of a woman burned upon the abdomen over an area of five by seven inches. Symptoms of peritonitis developed, and suppression of urine occurred. There was no movement of the bowels for a period of eight days. At the end of this time the wound became perfectly clean and at once all untoward symptoms passed away.

Burns over various parts of the body have at times caused abortion, also placenta previa as a result of the nervous shock; one case being reported of a woman burned over her belly, who was in the seventh month of pregnancy, at the time of the accident; on the fourth day acute peritonitis set in lasting four days; upon the eighth day, when the woman had nearly recovered from the inflammatory complication, labor set in and in seven hours she gave birth to a dead child. Upon examination bullæ were found upon the fetus.

Dr. S. P. Crawford reports a markedly similar case:

Inflammation of the lungs, pleuræ or bronchi following burns of the chest are common.

Brush burns and grazing missile wounds are often very like direct heat injuries; Mr. Horman says of the latter that they give an appearance to the skin as if it had been burnt by a hot iron rod. This is due to the removal of the superficial epiderm which exposes the true skin which turns brown after a few hours.

A peculiar complication resulting after a burn occurred in a patient of Dr. West's. A man, intoxicated, in falling, set fire to some fuses in his pocket and was burned over the lower part of the abdomen, the genitals and thighs as low down as the knees. The patient recovered, but with an extreme condition of phimosis.

A case of tetanus is reported by Dr. Godfrey as occurring in a man burned with phosphorus over the chest, hands and groin; symptoms began on the tenth day, with death in forty-two hours.

Fenwick speaks of a tendency to scarlet fever in children after burns. Two cases out of every eight observed by him developed the rash, throat, tongue and temperature symptoms of scarlet fever on or about the fourth day.

The commonly accepted designation of the severity of burns is that of Dupuytren, who made an anatomical classification of six degrees. Some surgeons, as Stephen Smith, Heath, Keen, Warren and White, make but three divisions, differing from him in that the burns of a severe type are grouped as one; while Gross divided them into complicated and uncomplicated, believing that it is owing to the many divisions into degrees of severity that so many forms of treatment exist (Holmes states that the treatment of burns is a subject upon which many books have been written and perhaps more numerous remedies recommended than in any other branch of surgery) and that by simplifying their description,

surgeons would become more uniform in their treatment.

I would divide burns into two classes, (1) all those which affect the skin, from slight inflammatory reaction following a scorch to destruction of the true skin; (2) all others, thus making involvement of the true skin the dividing line. The two classes may occur on the same person due to the difference in temperature toward the edges of the agent producing them.

The reaction of tissues to burns varies from the faintest browning of the glow of redness from a flame scorch, to black carbonization of the parts.

The variable effects constitutionally may be shown by a description of two contrasting cases which I saw in the Pennsylvania Hospital. A young woman was brought in burned over her whole body, excepting the palms of her hands which she had clenched. The burn was very superficial; her eyebrows, eyelashes and hair were but singed and over her body the burn extended no deeper than the epiderm. The woman in her night dress had upset a lighted lamp on the bed-clothes and though but a flash of flame thus momentarily enveloped her as she sprang from the bed, she died within four hours, shrieking her agony until subdued by morphine. The other case was that of a similarly caused accident to a man confined to bed with a rheumatic attack. He was deeply burned through the skin, subcutaneous tissue and fascia over his back from shoulders to buttocks. The whole sloughed looked not unlike a great sheet of lichened bark from an old tree. This man did well, was kept in bed but a few days, and then was able to walk to the clinic to be dressed, and went on to uninterrupted recovery.

The pathology of burns is the pathology of inflammation of the part locally affected, with almost all the morbid changes possible in the complications arising therefrom. A severe burn can open the way to the onset of many diseases, both medical and surgical, each fatal to life. From the grasp of the demoralizing fright of the moment of contact of the destroying element through the subsequent period of shock, followed by febrile action, internal congestion of brain, lungs or other organs, during the reactive period, burns may prove fatal at any time. Later, death may come from secondary hemorrhage, perforation of a duodenal ulcer, exhausting diarrheas or suppuration, disintegrating blood changes with absorption, causing pyemia, septicemia and embolism; also secondary parenchymatous inflammation of the kidney, with uremic poisoning and amyloid degeneration of the liver, spleen, kidney, and gastro-intestinal tract. Incidentally from without, erysipelas or tetanus developing may cause a fatal issue. Where life is not endangered, the local effects of ulceration, cellulitis, abscess, sloughing and gangrene, causing deforming contractions with loss of function, overgrowth of scars, sometimes involving nerves in the meshes of the fibrous tissue and slow healing ulcers, all handicap, thus giving this form of injury an importance which surgeons are prone to disregard.

The first action of heat is to stimulate sensory and paralyze vaso-motor nerve filaments, causing pain and hyperemia. This reaction may be instantaneously lost in severe burns as a result of loss of conduction where nerve trunks are involved, so that deep burns are less painful than superficial. This is well shown in the case reported of a foundryman who stepped one foot in a puddling-pot of molten metal with the result of complete solution of the member; he, however, suffered no pain. In a slight burn this stimulation causes an outpouring of fluid from the papillary loops of the capillaries in the corium. This bulges up the epiderm and forms vesications or blisters. Moist heat is more stimulating than dry, Neumann having found that moist heat from 167° F. will cause vesication, while 212° F. and over will destroy the skin in part or entirely. Much higher temperatures than these may be withstood if the heat and the portion of the body to which it is applied be dry, as illustrated in treatment by the application of dry hot air in certain cases to 400° F. or even 420° F.

The fluid contents of blebs or vesications is not serum, but serum plus fibrin ferment which in a few days if left alone causes an albuminous coagulation. The formation of this fibrin ferment is the cause of a rise in the body temperature and Horrocks speaks of a systemic poisoning action (non-bacterial), which develops at the same time.

Fluid and semi-fluid particles may both be absorbed from a burned area although, following the formation of granulations, little absorption takes place. The fibrin-ferment fever in simple inflammation is similar to the first rise in temperature after reaction in burns, not due to early sepsis. Horrocks says that there is first a period of quiescence before this reaction takes place.

Directly after a burn during the period of shock the temperature falls to 97° F. or as low as 95° F.; then rises at reaction to 104° F. or as high as 106° F. That absorption does take place he proves by reference to the action of the thermal cautery. He says we may for illustration divide the area of a scarified wound into three divisions, (1) the part most affected by heat; no water is present and the tissues are carbonized; (2) area of active inflammation; the vessels are plugged with clots and contracted, the lymphatic vessels retracting less than the venous and arterial capillaries on account of having less elastic tissue in them, absorption can readily take place; (3) area of active hyperemia, great diapedesis due to increased blood-supply, making it feel hotter and look redder than natural. Thus, in a simple scarification, we have an example of what occurs after a burn.

The mass of the eschar after a burn may be thrown off in either one of two ways, namely, (1) by a demarking inflammation with but little attending discharge which can be absolutely aseptic. Complete charring forms tar-like products of

distillation, which are naturally unadapted for infection of micro-organisms. The mass shrivels, mummifies and is cast off finally as a dry slough. (2) Infiltration of the slough due to activity of the micro-organisms which lying in the depths of the skin escape the heat's action; or due to those which wander in afterward.

The action on the skin causes it to become a yellowish, greasy pulp or to be thrown off in shreds and layers. A poison develops which belongs to the group neurin and muscarin, derived from cholin; their great virulency is shown by the action of muscarin, 5 milligrams injected causes symptoms of poisoning in a man. Putrefaction goes on, with water formation, the moisture extending into the tissues beneath, where these elaborated poisons are readily taken up and carried into the general system. A rich supply of oxygen favors their development; oxygen being necessary to produce virulent ptomains.

Deep burns are relatively less dangerous than those superficial burns which produce white eschars. Over a given area a scald or a flame scorch will cause less destruction than does fire, while molten metals burn deepest.

The early visceral changes after severe burns are well shown by Dr. Russel who reported the postmortem findings in the cases of five children who died a few hours after the accident. The liver and kidneys were swollen, spleen enlarged and softened with moderate hyperemia of all the organs. Most striking was the swollen appearance of the lymphatic glands and the gastro-intestinal lymph-follicles. Focal changes about their germinal centers had taken place wherever lymphocytes were found, from the small nodules in Glisson's capsule to the largest lymphatic glands. The germinal center was enlarged so that it could be seen by the unaided eye. The protoplasm of the cells was broken up, while certain endothelial cells in the neighborhood, acting as phagocytes, had taken up the fragments of protoplasm and nuclei. In the blood, fragmentation of the red blood-corpuscles, especially in that taken from the spleen, somewhat less so in the liver, had taken place. In the skin thrombi appeared and in the Malphigian corpuscles the same changes had occurred. Russel explains these various changes by assuming that toxins elaborated by destruction of the superficial layers of the skin pass into the circulation, and when the arteries of the lymphatics break up into capillaries the rapid flow of plasma causes the edematous swelling and tends to sweep the lymphocytes into the pericuticular lymph-sinuses.

Nearly identical changes to these have been found in the lymphatics of children dead of infectious diseases. Frankel and Spiegler implying the same principle in their statement that the fatal effect of burns is due to intoxication from absorption of pathological cleavage products of the body proteids; death being therefore due to an acute toxemia.

That grosser lesions may result from these causes is well shown in a case reported by Dr. Granges of a boy of eight years who was burned by a redhot coal falling from the fire and rolling over his arms, belly, genitals and legs. Death occurred on the fourth day from a fibrinous clot found in the longitudinal sinus.

Fenwick holds that early death and internal complications after burns are due (1) to alteration in shape and diminution of vital properties of the red blood-corpuscles. Schultze found at a temperature of 54° C. (119° F.) that red blood-cells became shriveled and partly disintegrated, thus losing their power of carrying oxygen when most needed; also an abnormal loss of body heat occurred, due to paralytic dilatation of the blood-vessels and the fact that blood being a good conductor of heat, destruction of the epidermis, a poor conductor, allowing the loss to take place. (2) This fragmentation causes thrombi and stasis in the lungs, kidneys, intestines, liver, brain and subcutaneous cellular tissue. Thrombi are most numerous in the terminal branches of the pulmonary artery and are found during life. This causes obstruction to the emptying of the right ventricle and therefore general arterial stasis with consequent arterial anemia.

These conditions cause hemorrhages. Sometimes cardiac thrombi occur alone, giving rise to precordial pain, irregularity of the pulse, with obstruction of the pulmonic circulation and dyspnea rapidly increasing until death, ulcerations, and parenchymatous changes in various organs. Thus may be explained dyspnea, cyanosis, coma, smallness of the pulse and the various lung affections, convulsions, anemia and fall of body temperature after severe burns. The fatal issue after small burns in children is due to (1) a more intense action of heat upon the corpuscles; (2) weaker resistance, owing to the thinner skins of the corpuscles; finally, the comparative weakness of the heart and circulatory apparatus generally. This is borne out in fact by the report of an examination of a child, two years old, scorched over the upper part of the body, who died comatose after twenty-four hours. At the postmortem there was found congestion of the lungs and the brain membranes; arachnoid fluid in the ventricles, with engorgement of the vena cava and the right heart.

Convulsions are often the symptomatic cause of death in children, owing to their greater nervous susceptibility. When the blood changes come on quickly, excess of function is excited; but when some time has elapsed, structural changes take place.

Erichsen in examining 119 fatal cases of burns found complications affecting the brain in 33 out of 37 examined, complications of the viscera in the chest cavity in 30 out of 40 cases examined and of the abdominal organs in 31 out of 42 cases.

Dr. Jenner has described the postmortem findings in 17 cases of burns, the victims of a tenement fire in London; they were of all ages and of both sexes. Cadaveric rigidity had rapidly taken place and was due to cooking of the mus-

cles with shrinkage after death. This caused extreme flexion, which took great strength to overcome, recurring when pressure was removed. Dr. Jenner thought that in some instances where extreme shortening had taken place, an antemortem convulsive contraction had occurred before fixation by heat coagulation. The claim agent of one of the eastern railroads detailing to me the account of an accident which occurred on his road several years ago in mid-winter, when twenty-two passengers were burned and scalded to death, stated that it was impossible to straighten their flexed and contorted bodies. The jaws were found to be firmly clenched, so tightly in some cases as to cause blood to exude from the tongue. Excepting in a few cases the blood was found fluid in the heart. The liver, spleen and kidneys, all much congested, with dark, venous blood. The bladder was found contracted. The mucus in the nose and throat was of a blackish color, due to smoke and inhaled carbon particles. The lung tissue was of a rosy tint. Burned areas which had occurred after the death of the victim had no red halo surrounding the charred area as did those which caused death. One man was found with bits of plaster in his mouth and throat, with mucus black from carbon: this in connection with the presence of charred burns, without inflammatory halo being found proved conclusively that the man had been smothered by smoke and noxious gases and not burned to death. A medico-legal point of great importance; could be thus settled with ease. In this connection a practical point may not be amiss; firemen are often enabled to go long distances, through smoke and combustion gas filled rooms and halls, by creeping close to the floor, as the heavier uncharged air occupies a space of a foot sometimes as much as two feet above the floor. Bloody fluid was found in the pleural cavity and in the pericardium, though not over half an ounce was found in any one case.

The function of internal organs is to take on the extra work of the destroyed skin after burns; Freund and Russ have shown that the urine of those badly burned contains pyridin which Fraenkel has obtained by decomposing albumose with sulphuric acid; hence it seems possible for heat to cause a similar action in the bodies of patients. These authors have studied the urine in four cases of fatal burns and always found three abnormal constituents. The first is a series of bases of the pyridin type. The second is cysteine or is closely allied to it. The third from its reactions seems to belong to Pavey's group of carbo-hydrate derivatives of proteids. The urine was free from albumin and nucleo-albumin.

The author's theory requires for substitution the artificial preparation of these substances from proteids and the study of their effects upon animals; an important clinical fact seems to be that their presence in the urine is of grave import.

The degree of body temperature seems to be a factor in the production of kidney congestion. This is shown by reports of clinical examination made daily and systematically over long periods of time, at the Pennsylvania Hospital. It was demonstrated that when the temperature in a given case was below 101.5° F. in burns of whatever extent or severity, no albumin was present in the urine. Where kidney congestion is a special complication, albuminuria and hematuria are due to the acute nephritis. Amyloid change in the kidney after long suppuration may alone be the cause of albuminuria. Glycosuria coming on acutely and lasting four weeks is reported in one case after a slight burn.

The course of a burn is of importance to the surgeon from its very inception. He has not only to deal with local wounding, but with a constitutional reaction on the part of the individual injured as well. Under the head of shock are these constitutional manifestations described; and to it must be ascribed the chief cause of early death after burns. According to Shrady shock is a jar to the equilibrium of the entire sympathetic system, of which mere pain is oftentimes an insignificant part. Mitchell, Morehouse and Keen add to this enfeeblement of the heart's action through the mediation of the medulla oblongata and the pneumogastric nerves.

In a group of ten cases of burns occurring at one time, reported by Ashhurst, six died of shock within the first twenty-four hours.

A. E. Durham and Bryant agree that shock kills one-half of all fatal cases of burns. While young people stand shock very well, as do females better than males, infants and nervous women are very susceptible to its influence. The causes of shock are dependent upon the nature and extent of the burned wound. Burns of the chest and belly cause greater shock, other things being equal, than do such injuries of other parts; again, burns cause greater shock than do scalds. In Bartholomew Hospital, during a period of ten years, burns were found more fatal than scalds in the proportion of 26 per cent. to 9 per cent.

Pain, fright and loss of body heat are factors in the production of this condition. Heath believes that shock is kept up so long as there is any pain present, and Sonnenburg states that the sudden irritation of the sensory nerves, so numerous over a burned area, may be followed by paralysis of the heart, which, superadded to overheating of the blood, explains the sudden early death after cases of superficial burn. Lustgarten holds to the theory of intoxication, following burns of cutaneous surfaces when early fatal. Sonnenburg, however, contends that in as much as Lustgarten's cases all had an eschar, death was due to overheating of the blood, with consecutive thrombus formation. The temperature in such cases will rise a few tenths of a degree; there is an interval of cerebral and spinal irritation, followed by symptoms of paralysis and coma, all simulating alkaloid poisoning.

The symptoms of shock do not always appear at once; the period of depression following these injuries is given by most surgeons to be about 48 hours. Fell states that the time for the

appearance of shock may vary from 1 to 48 hours, and during this time the patient may be moved without harm.

During the period of depression the temperature falls and the patient feels cold and shivers; pain is oftentimes continuous. Following this is the period of reaction, lasting at times ten to fourteen days, and characterized by an elevation of temperature and internal congestions. An insatiable thirst is often an accompaniment and when the stomach is unretentive, adds to the dangers of the condition.

Fenwick, speaking of this complication from his experience in London Hospital, says it is an axiom at that institution that if a burn case vomits soon after admission, it will die. Hebra, Sr., and Kaposi, with their great experience in these injuries, state that they never saw a recovery after vomiting had set in. It is during this period that duodenal ulceration occurs; a complication to be more fully dwelt upon later.

Following reaction, the patient passes into what surgeons generally are pleased to call the stage of exhaustion. During this time more or less suppuration is taking place, and there is danger of death from exhaustion alone. Extraneous causes, such as erysipelas or tetanus, may be superadded to the suppurative process or to visceral damage. Diarrhea very often appears as the immediate cause of death.

A complication to which Curling, before the middle of the last century, first directed attention is ulceration of the duodenum. He noted that it was common in children and that when it occurred it was dangerous, death being due to hemorrhage, or to perforation and peritonitis. The cause of this lesion according to Curling, was an attempt upon the part of the adenoid tissue in the duodenum to assume the function of the destroyed skin. Since his time, many cases have been reported by others and must study and endless discussion as to the cause of this lesion have resulted. That it is not so common as it is important when it does occur is shown by the following statistics from Guy's Hospital in which, of a series of 37 fatal burn cases, 12 dying between the third and sixth days, examined for this lesion, no intestinal inflammation was found.

Holmes in a report on 125 postmortem examinations after fatal burns found 16 patients with ulcerations of the duodenum. Of these 5 died on the fourth day, 5 during the second week and 6 at a later period. At Bartholomew's Hospital 138 deaths from burns, with postmortems, took place in ten years; of these but three cases of inflammation of the gastro-intestinal tract occurred. In London Hospital, Dr. McCarthy saw but 2 cases of duodenal ulcer in 8. Erichsen reports 2 deaths from duodenal ulceration, after examination of 68 cases of fatal burns; and in another series of 22 cases in which postmortem examination of the abdominal organs were made he found them healthy in 5, generally inflamed with some trace of peritonitis in 11, duodenal ulceration in 6 cases.

The cause of this ulceration according to some surgeons is unknown, others believe it is due to poisoning of the adenoid tissue, especially that of the duodenum, which comes from the blood, or is thrown off by the liver in the bile. This explains why the ulcer is found most often in the pouch of the duodenum, placed posteriorly, just below the opening of the common bile-duct. This theory was supported by Wm. Hunter who used the following experiment to show that poisons generated by absorption of matters from the site of a burn are the cause of duodenal ulcers. He injected subcutaneously in a dog from 3 to 5 milligrams of toluylendiamin and later examined the viscera for pathological changes. In animals thus treated an intense duodenitis was found, due to the excretion of the poison by the bile. Hemoglobinuria occurred after the injection of the drug, as it does after certain burns.

Another theory and one which I think is well borne out in fact, is that of thrombus formation. It has been well proven that fragmentation of the red blood-cells occurs after burns and that semi-solid particles are absorbed and carried into the circulation. It is an incident whether the thrombus be carried to the duodenum or to some of the other viscera; after the capillary embolism has taken place, antemortem digestion completes the process of ulcer formation.

In my readings upon this subject I have found many descriptions of duodenal ulcers, but no clear narration of cases where this lesion occurred alone. Grange reports his findings of a suspected case of duodenal ulcer; a man burned variously over the body to one-sixth of its extent died on the fourth day. At the postmortem examination no duodenal ulcerations were found, but disintegration of the stomach had occurred.

Tay reports the case of a woman, aged forty-eight years, burned over the chest, neck and face, by a paraffin lamp. The most prominent constitutional symptom was pyrexia; death occurred on the twenty-fifth day. Upon postmortem examination of the arch the aorta was found full of coagula; the valves and heart were normal. Two ulcers were found on the curve of the stomach, but no lesion of the duodenum was found. It would seem in this case that the continued high temperature gave rise, as borne out by the experiments of Schultze, to an increased tendency to fragmentation and clotting of the blood.

Another case is reported of sudden death after a burn from hemorrhage of the stomach. Upon postmortem examination no gastric ulceration, but congestion of the mucosa of that organ was found. In the duodenum, neither an ulcer nor congestion were found.

Carhart records a case of suspected ulcer, with recovery, after a burn which extended over a total area of six square feet. After four days the stools became clay-colored and of a cadaveric odor, with the symptoms of a duodenal ulcer developing. The patient laid on his back most of the time, and while healing was protracted, bedsores forming, the patient recovered.

Hill reports a typical case, following a scald of the legs, back and buttocks of an idiot girl, aged eighteen years; death occurred eighty-three hours after the accident, vomiting having come on after twenty-four hours. At the postmortem, a perforating ulceration the size of a shilling was found on the posterior surface of the bowel two inches from the pylorus. Its edges were pulpy, somewhat thickened and adherent by plastic lymph to the head of the pancreas. The surrounding peritoneum was inflamed. The stomach was found empty, slightly injected and inflamed. The lungs were somewhat congested. No hemorrhage occurred from the bowel.

A case of frostbite is reported to have finally ended in death from duodenal ulceration, as was proven by subsequent autopsy.

Symptoms of ulcer formation are usually meager. From descriptions of the suddenness of the onset of the condition, a study of the temperature is important. A sudden fall occurring especially between the fourth and twelfth day should excite grave suspicion; the time cannot be set down as unvariable, however, as a case is reported as occurring one hundred days after the accident. Ulceration, however, occurred in the large intestine. This subsequently healed.

Annandale reports a case of death from duodenal ulcer on the seventy-fifth day after the burn was received, the fourth day of tne ulcer. Holmes recites the history of a patient of his whose death occurred from a duodenal ulcer, three years after recovery from the burn had taken place.

A typical duodenal ulcer, following a burn, takes the form of an indolent, circular, non-indurated, punched out ulceration and when deep, lymph is thrown out upon the peritoneal surface, offering thereby a natural protection from perforation; or, after a perforation has occurred, plastic lymph may at times be thrown out in sufficient quantity to occlude the opening. When ulceration into one of the duodenal blood-vessels occurs, fatal hemorrhage is the rule, likewise, connection with the serous cavity of the peritoneum with a developing peritonitis will cause the death of the patient. From the fact that cicatricial ulcers have been found in patients who died of complications after burn injuries, the importance of a given case will rest on the amount of surgical injury produced.

Contraction after the healing of burned wounds is of common occurrence. The depth of the wound is not the chief factor of its production for many burns which extend only through the skin have been followed by the greatest contraction. Friction during healing is the principal factor. It is for this reason that burns over the flexures of the joints are especially liable to this complication. The greater the friction caused by muscular movement (applications or dressings, must be added as a source of granulation irritation) the more exuberent will be the granulations. The larger the granulations, the greater will be the amount of connective tissue and the more will be the contraction.

Treatment.—Deaver has stated that every medical book is a rehash of what has gone before, but this must ever be so where true advance is made. The foundation of medical science has been laid and what is to come needs no firmer base. A man writes surgery because he thinks he has learned how to do things and wants to tell others how well they can be done. I have no new theory to present in regard to the treatment of burns. Many and varied have been the methods of treatment suggested and advised for these injuries; from the cook's dredger to complicated germicide mixtures, the underlying principle has been the same, namely, to prevent mechanical irritation of the surface of a hypersensitive wound and allow granulation to go on unhampered.

Hippocrates secured the least friction, consequently obtained the best results, in his treatment of burns by using lard and aromatic oils; to-day, carron oil is the common remedy for burn wounds. Oily applications to burns have the disadvantage of becoming rancid and dissolving otherwise aseptic sloughs which are dry from charring, and allowing infection to take place through the sloughing mass. Dressings become saturated and dry with a crust which causes irritation of the wound surface.

Gross found that carbonate of lead mixed with oil, common white-lead paint, applied to burns added to the value of mere lubrication by providing a support for the granulations; thus carrying out the idea of scab formation in wound healing. The coagulation of the contents of vesicles and the serum poured out upon the surface of a burn wound is plainly Nature's attempt to form a base for granulation formation, but pus infection too often mars the plans. Guzzo helped scab formation by using glycerin. Bilroth employed a solution of 2-per-cent. silver nitrate, painting over the whole wound. He stated that, though very severe pain is sometimes caused by this method, an eschar is formed and healing takes place more rapidly than by other methods of treatment. Skey uses a 10-per-cent. solution of the same drug, with a similar object in view.

The danger of using the silver nitrate eschar as a protective and support for granulation lies in the fact that infection will take place beneath it and being confined increase the irritant action of the pus organisms.

Velpeau found that pressure by adhesive straps would promote healing, and by this means secured support for granulation formation. Druitt followed out the same principle when in burns which refused to heal he employed a sheet-lead plate cut to the size of the burn and held in place by adhesive plaster. He gave absolute rest o the part, prevented friction and the burns got well.

As a friction protective silver-foil has lately been employed in the treatment of burns at the Johns Hopkins Hospital.

Picric acid in various solutions has been advised as an early treatment for burns before granulation commences; it is said to deaden pain.

Heath forms a scabbing solution by mixing one part of collodion with two parts of olive oil; using it especially for burns about the face.

Pure carbolic acid in solution, lately advised by some surgeons to be painted over burns, counteracts its virtues by being often very painful and by causing additional eschar. Although the intention is to cause a sterile, superficial eschar to be formed over the surface of the wound, we cannot be positive that micro-organismal (pus) growth has not taken place beneath the slough. It is therefore not a wise procedure to so seal up a burn wound.

Copeland reports two cases which were treated in an orignal manner by him along the same lines. The first patient was a man whose face, ears and hands had been burned in a boiler explosion. He had been treated with cotton and cosmoline dressings daily with no benefit and was in great pain, with wounds freely discharging. By the use of mosquito-netting the face was protected, and from pasteboard the doctor constructed open-end boxes in which the hands were placed and so held by means of plaster that they did not come in contact with the pasteboard; the ends were covered with netting to keep off the flies. No other dressing was used. By the next day all discharge had ceased, pain had disappeared, and there was glazing of the open wounds. Recovery commenced at once and was uninterrupted, leaving little disfigurement. The second case was that of a little girl, aged two years, whose clothes catching fire, was burned on one of her thighs over an area of two by three inches. Household remedies caused the wound to do badly; at the end of two weeks, fever developing, Dr. Copeland was called. He formed an oval pasteboard cover retained in place by adhesive straps, which he left over the wound for three days. Upon removal he found a well-formed scab, no fever, and healing well advanced.

By a study of the principles which underlie these different methods of treatment, we can arrive at but one conclusion. Secure protection for the granulations forming over a burned area and we will obtain a perfectly healed wound. There will be no danger of distortion of the scar or loss of function from contraction. Dusting powders of all kinds are as foreign bodies to burns and prove their irritant properties by the amount of discharge they cause.

Constitutional treatment of a patient burned is of the greatest importance and would naturally come first in a study of these injuries; but as I wish to direct attention to the treatment of a burn considered as a wound, I place it last.

The commonest and most dangerous source of irritation to a burned wound is infection. Suppuration has been considered by most surgeons as inevitable and, until Morton and Morris began advocating antiseptic treatment of these wounds when first seen, nothing was done to prevent this condition. The latter surgeon writes strongly and says common wound principles are "shamefully neglected" by the profession in these cases. These gentlemen, however, do not advocate frequent changing of dressings of burns and I find this teaching general in the writings of the profession. Morton states the great principle in the treatment of burns to be to allow the dressings to remain on as long as possible. Morris believes that frequent dressings are not only uncalled for but injurious.

From time immemorial it has been taught that air is an irritant to a burn and the common practice of some surgeons is, when dressings become saturated with discharge, to apply more dressings, externally, without removal of those beneath. Air is not an irritant to a burn and a burn wound which has been buried under layers of pus-soaked gauze or cotton batting for days is the better for removal, without fear of what the presence of air may do or that pain will be caused.

The pain of a burn is due to the direct action of heat upon the terminal sensory nerve-endings; continuous subsequent painful manifestations are due to the irritation of sloughing tissues, applications of dressings. The question of pain occurring when burns are dressed depends on the care in which the dressings are removed, and what the nature of the dressing applied next to the wound surface has been. Gauze, patent lint or cotton, dry and stick fast to this form of wound, as to any other where there is any oozing, and will irritate the granulating surface so long as it is on, causing pain when removed at the first dressing or at any subsequent one. The only danger which could arise from removing dressings and uncovering large burned areas is that from loss of body heat following destruction of the epidermis before constitutional reaction has taken place. As a laparotomy wound becoming foul-smelling from discharges is not treated by piling on more dressings, no more should a burn. Seeking to defend his position, one surgeon, speaking of the discharge and odor which follow his treatment of burns with carron oil to which he adds iodoform, states that when a surgeon gets disgusted with the odor so that he is unable to endure it for the sake of his patient, who if seriously burned will not complain of the odor, he had better take up the occupation of horticulture as being more properly within his (nasal) sphere. This gentleman advises few changes of dressings to be made. Handled thus, burns will verily continue to be, as they are usually described, "filthy" affections to treat. It is painful to remove a drainage-tube from a through-and-through drainage of an abscess, yet a clogged tube is useless and becomes the determining factor of the temperature-curve tracings of that case. Aseptic surgery is the ideal toward which we strive; the surgeon who fails to keep clean (free from infection) until healed the wounds of the body which he makes knows he has fallen short and will strive in his future work to correct the faulty technic which allowed such invasion. Burns and scalds are wounds, as much so as an incision or a laceration, and demand as careful treatment. The earlier a burn can be dressed the better will be the result.

Of the household remedies it is sufficient to say that they should not be used. Friends would do best by the patient and assist the surgeon if they would confine their efforts to carefully cutting away whatever clothing was loose about the burn, wrapping about the wound a piece of oiled or wax paper, such as florists use, tied on with strips of muslin. A burn wound so handled is in the best condition for right treatment by the surgeon.

Removing the oiled paper protective; with scissors and forceps cut away all shreds of burned clothing remaining about the wound. Puncture blisters and drain fluid which either will be rapidly absorbed with a febrile reaction or coagulating, awaits but the entrance of pus organisms to become a culture medium. Infection being ever present in the skin, by trimming away all detached fragments a source of danger is avoided. With care cut away as much of the burned subcutaneous tissues as possible; a curette may be necessary and when gently used will cause but little pain. An anesthetic is advised by some surgeons to be used when large, deep burns are to be dressed, and if it does not increase shock it may be useful at times. All of the burned tissues will not be removed at one dressing; inflammation must assist in the removal. Disorganized, dead, burned tissues must be cast off from the living, but we now know that the aid of pyogenic organisms are not needed to further this process.

In selecting an application for a burn, two principles are involved; the agent must cause no irritation and must be antiseptic. The most commonly used antiseptic drug in wound treatment is bichloride of mercury, but in hydrogen di-oxide we have that which to my mind is almost the ideal wound cleanser. According to Houssell of Tübingen a 3 per cent. hydrogen di-oxide solution is equal in power to a 1 to 1,000 bichloride solution, acting on bacteria suspended in aqueous solutions; but hydrogen di-oxide is superior to it in media rich in albuminous fluid, but poor in cells. Where the latter predominate it is again on a par with the solution of sublimate.

Bichloride solution of 1 to 2,000 strength applied to burned areas is often too painful to be borne and in children has caused convulsions. Carbolic solutions, boric acid, sodium bicarbonate or the like, in the strengths advised to be used on burns are too weak to be of value and but add to the moisture of the part; if used stronger they become irritants and increase discharge.

Having cleared up the wound, it is next to be thoroughly washed by syringing with a solution of hydrogen dioxide, one part to six of distilled water. I have many times used a full-strength solution without causing pain, but routine treatment had better be commenced with weaker solutions. Much dead tissue will be dislodged and washed away in addition to that removed with instruments. When foaming has practically ceased commence the dressing of the wound by applying all over its surface and well over the edges to sound skin strips of rubber tissue in size about ½ to ¾ of an inch wide by three or four inches long; each strip to overlap the previous one laid down by a small margin. Rubber tissue is now made membranous in quality and it is this form which will lie best and cause least irritation.

A few layers of loose, sterile gauze is to be fluffed over the tissue and the whole held in place with a gauze bandage or by means of two or three narrow adhesive strips. To secure perfect rest we must place the part in the best position to obtain muscular relaxation, applying splints for retention and support. They should be well padded and held to the part by adhesive plaster, over which should be applied a muslin bandage to complete the dressing.

Dressings must be so disposed that no pressure upon the forming granulations will result or irritation will be caused. Barber uses rubber tissue in large sheets, wrapping it around the limb, as he says "the tighter and more snug the better will the air be excluded and the quicker will be the recovery"; over this he applies absorbent cotton held on with a roller bandage. Where destruction of muscles, tendons or their sheaths has taken place after burn injuries, the mechanical balance of the mechanism of the joint affected will be destroyed with a commensurate loss of function dependent on the extent of the injury. In such cases the best we can hope for is ankylosis in a good position for future usefulness.

Dr. J. Webb, speaking of the hopelessness of the local treatment of old burns about joint flexures, which are ever contracting and breaking down, advocates radical surgery. One of his cases was that of a man suffering for twenty-one years with a burn of the popliteal space which refused to heal and destroyed the function of the joint. The second case occurred in a woman and consisted of a burn over the elbow, extending but through the skin. This wound healed and broke down continually, as did the other. Amputation was performed in each case. The patients did well and were decidedly less crippled after the operations than before.

There are cases which will require amputation after burns, but they will become fewer when the fresh wounds are given the careful attention which they deserve. The case of my own, which was the cause of arousing my interest in the treatment of these injuries, was that of a man burned on the outer side of the arm, over the bend of the elbow and the front and inner side of the fore-arm half way down to the wrist. The burn extended into the cellular tissue beneath the skin. Treating this wound as I have described, the scar tissue which formed during healing partook so closely of the nature of the normal tissues that a perfectly restored arm was the result. A subsequent case was that of a man suffering from a scald of hot water over the front

of his left leg, ankle and instep; carron oil had been used for three days before I commenced treatment of the case. With hydrogen dioxide, in full strength I syringed the wound, thoroughly washing away the masses of organized exudate and shreds of dead tissue, and trimmed away all of the blebs and loosened skin covering the scald. Rubber tissue strips were applied with gauze and bandage, as described. Pain, which had been a prominent symptom, and the discharge stopped at once, and though I had great difficulty in preventing movement of the ankle joint, as the patient returned to work after the first dressing, healing commenced immediately and went on to rapid recovery with a resulting scar which was freely movable and non-contracting. The granulations in both these cases were minute and closely packed from the commencement of the treatment until they leveled off and became permanent tissue.

The number of times that a burn should be dressed will depend on the amount of discharge which comes from it after the wound has been cleansed. Where there is danger of parts burned touching each other, they must be dressed separately to prevent distorted growth, particularly in the case of burns about the fingers and toes. To secure good results in burns of the hands of young children great care will be necessary. Burns of the palmar surfaces will require careful splinting until perfectly healed to obtain the best results. In such cases a posterior splint with a pad placed and held with adhesive straps so as to produce extension, is best. Cases which have done badly had better be left until the child is five or six years of age before attempting plastic work. In burns about the lax tissues of the neck and over the flexor surfaces of large joints, immobilization by whatever means it can be best obtained is of special importance. A burn about the neck which destroys the skin requires absolute rest and, as in fracture of the clavicle, the result will depend on it.

As surely as we can mark the growth of large, angry granulations, so can we tell what the result will be in after-time when the patient returns with a terrible contraction. The application of caustics or powdered pepsin is but an attempt to balance friction and contraction and too often fails. Plastic surgery will step in and change the current of events, but ours is an era of preventive medicine; attention, therefore, during the early formative (healing) stage to the wound, along the lines of common surgical wound treatment, will be effective and such cases will become known from their rarity.

Burns of the face are described as generally doing well and cases are reported as healing without a cicatrix, even when deep ulcers were present, while similar injuries upon the extremities do not do so well, taking longer to heal without securing as good results. The idea of an extra blood-supply in and about the face causing wounds of these parts to heal quicker than those of other parts of the body is fallacious. Practically all tissues have capillaries and it is these vessels which are the important factors where healing is taking place.

I have found a wound of the back or the leg equally deep as one of the face or scalp to heal as quickly as the latter when I have secured rest and freedom from irritation. Again, I find in my work that when I am not clean in a wound treatment, those of the face or scalp suppurate as quickly as do other parts.

Every individual has powers of healing equally developed over his body. Rest of the part, in its broadest sense, is the factor in the production of quick healing of a wound. An individual in repose or in activity will not move the facial muscles as much as his hands or legs if suffering from a wound of the face, hence the diversity.

Burns of the mouth and throat will require active treatment, which should be begun as soon as possible. Carbolic-acid burns of these parts, treated at once with alcohol, pure or dilute, as the requirements of the case call for, will promptly save life or prevent future constrictions. In cases of carbolic-acid burns from swallowed acid, we must remember that the antidote alcohol is a poison in itself requiring immediate lavage. Death occurred where this was neglected in the case of a child who having swallowed carbolic acid was given three and a half ounces of alcohol.

Edema of the parts should be treated by hot baths and diaphoretics; if no relief is obtained, scarify the base of the tongue, and pharynx, puncture the epiglottis and the sides of the larynx with a curved bistoury, guarded by a finger and wrappings of adhesive plaster or cotton; afterward use hot gargles and apply poultices to the sides of the neck. As a last resort, based on the fact that edema does not extend below the vocal cords, Ashhurst recommended the operation of tracheotomy, himself having performed it for edema of these parts after mouth and throat burns of various kinds twenty-eight times with five recoveries.

Lime splashes in the eye should be treated by dropping water acidulated with vinegar into the conjunctival sac. Copious irrigation by means of a strong force of water is often the best remedy. Particles should be removed with the moistened end of a handkerchief or a wisp of cotton twisted on the end of a match stick.

The treatment of burns due to the action of electricity in the production of the X-ray calls for absolute rest of the part and drugs to overcome pain, as shown by the case reported by Orleman. The burn took the form of an ulcer which refused to heal for ten months in spite of many forms of treatment, and was finally determined to be a trophic neuritis. A case has been noted in an English medical journal, which

came to coroner's inquest alleging death from Roentgen-ray photography. A woman suffering from fracture of the thigh-bone in March, 1900, was exposed upon the sixth of April to X-ray examination for two hours and twenty days later to a like exposure lasting two hours and ten minutes. "The latter exposure was followed by inflammation, and, so far as can be gathered from the newspaper reports, by ulceration of the abdominal walls." The woman became mentally unbalanced and death followed.

The sun's rays may cause burns of the first degree of severity. If attended to at once before vesication has taken place I know of no better remedy than that of Dr. Wood, as follows:

℞ Vinegar or dilute acetic acid, fl. oz. j.
Glycerin .....fl. oz. j.
Bismuth subnitrate, q. s. ad to paste.
Sig. Apply to burned parts.

Where vesication has taken place the treatment is the same as for other burns.

F. Mulig reports two cases of systemic poisoning following the use of bismuth subnitrate as an application for burns. In one case the treatment had been carried on for nineteen days, in the other for twelve days, when the patients began to suffer from stomatitis, salivation, blue line on the gums, and dysphagia. In both cases a thorough curettement of the wounds was necessary and a months passed before the symptoms entirely ceased. I think we need have no fears, however, of poison symptoms arising from the use of bismuth in this prescription for sunburn.

Skin-grafting is an important adjunct to the treatment of burns when large areas of skin have been denuded. Bryant lays great stress upon this procedure. McBurney, in skin-grafting for this and other forms of injury at Roosevelt Hospital, after clearing away and rendering the wound aseptic, employs rubber tissue as a protective in the form of shingles, in order that the salt solution, with which the gauze is wet may penetrate to the grafts. The rubber tissues, after being washed, is used again at subsequent dressings. Common oiled muslin was tried and found to be dry, stiff, hard and irritating; cotton batting was condemned on account of sticking and being irritating to the parts.

The constitutional treatment of a patient burned should be begun by placing him in a well-warmed room, in a bed screened to prevent drafts. Pain is the first symptom to be combated by the use of opium. To an adult, ¼-grain doses of morphine sulphate should be given at intervals of thirty minutes, until the pain is controlled. We must remember that it is the pain which we are treating and while pain is present we will not reach the therapeutic limit of our drug. Often ½ of a grain will be needed as a first dose. I have neither seen nor heard of harmful results from an overdosage of this drug while pain was present. Should such a case arise we have but to employ the antidote for opium, which is cocaine in sufficient dose to overcome its action. To an infant give 2 to 4 drops of tincturæ opii or tincturæ opii camphorata, repeated at intervals of thirty minutes until quieted. Naismith advises the use of ice cold baths to the burned parts as a "preliminary" treatment until pain has passed away.

In Vienna a treatment is followed out which consists of immersion of the burned parts in water kept at the normal body temperature. Shock coming on the patient complains of cold. Blankets, hot bricks, bottles or bags are the external requisites to promote reaction. At once may be given hot drinks; such as brandy in one-ounce doses, strychnine gr. $^1/_{30}$, atropine gr. $^1/_{50}$. Baxter advises for shock, baths at a temperature of 95° F. continued for periods of two hours. Von Nussbaum advises baths at 100° F.; he says this treatment has decreased the mortality of burns in the hospitals of Germany.

Vomiting coming on during the course of a burn is at all times serious and, while it may occur at any time, it is particularly liable to appear with the reaction of the body from shock. The patient becomes very thirsty and great care must be used in the quantity of liquids given; thirst should be quenched with cracked ice. No liquids or medicines are to be given by the mouth. The strength of the patient must be kept up by rectal feeding.

Brieger reports a case successfully treated by atropine sulphate given hypodermically. His first patient suffered from an extensive burn of the first degree caused by clothing catching fire; he was placed on a Hebra water-bed during treatment; on the second day vomiting began. Five milligrams of atropine sulphate were given during the course of the next two days. Vomiting ceased after the first injection; all threatening symptoms passed away and the patient recovered. In two other cases this treatment kept vomiting in check for hours, but did not prevent fatal termination.

Atropine is an antidote for muscarin. Brieger's theory is that by learning the nature of the ptomains given off in burns poisonous atom groups may be introduced which will unite to form non-poisonous compounds.

The bowels and bladder will oftentimes require continuous attention. The surgeon must bear in mind the danger of setting up a diarrhea after burns by treating constipation with aperients; enemas should be the only means used. The internal treatment of ulcers, should they develop, includes treatment for relief of the kidneys, diuretics, stimulants, with a milk diet. If uremic symptoms arise, produce diaphoresis.

During the period of reaction when everything must be done to support the patient's strength at this time internal congestions must be watched for and treated actively. Now, too, is the danger from pyemia from the

patient being allowed to lie in a bath of pus of his own making and absorption taking place; frequent dressings of the burned parts is the preventive treatment.

Hopeless cases of burns may be put in the continuous Hebra water bath, or the burned parts wrapped, as suggested by Dawson, in sheets of rubber tissue, oiled paper or oiled rubber tissue.

Summary.

Burns are the commonest of injuries and of all wounds they are treated least in accordance with now universally taught and accepted surgical principles.

Burns may be divided into two degrees of severity; burns of the first degree involve the skin only, those of the second degree include all others.

The pathology of burns is the pathology of inflammation of the part locally affected with almost all the morbid changes possible in the complications which result.

Early death and internal complications after burns are due to direct action of heat, with fragmentation and vital change in the blood-corpuscles; later effects are due to infection taking place from the burned area.

The condition of the granulations during the healing of burns is the determining factor in the amount of contraction and subsequent deformity which takes place. The greater the friction caused by irritation from whatever source, the larger will be the granulations, the greater the amount of connective tissue and the greater will be the contraction.

The local treatment of burns from the earliest times has been along the lines of prevention of irritation, but the late advances made in wound treatment have not been followed out in these.

The burn wound should be cleansed of as much dead, burned tissues as possible; the thoroughness with which this clearing away of the eschar is done will determine in a great measure the amount of future discharge, and the presence or absence of infecting organisms.

Hydrogen di-oxide to wash away the débris and render aseptic the denuded parts is the best antiseptic at our command; rubber tissue in strips should be laid on the wound to prevent contact with the absorbent dressing.

The use of splints to secure relaxation and retention in obtaining rest for a burned part is of great importance and is as much indicated in this form of injury as in fractures of the contiguous bones.

The internal treatment of burns is stimulative until reaction from shock has taken place when it becomes supportive.

Opium fulfils the indications for pain, internal inflammations and diarrhea.

The bowels and kidneys must be continuously kept open, but enemas only should be employed.

Watchful attention must be paid for early signs of internal complications of the viscera.

805 Madison Avenue,

CARBOLIC ACID IN BURNS.[1]

BY OTTO L. MUENCH, M.D., PH.G.,
OF WASHINGTON, MO.

SOME years ago I chanced to read in one of the medical journals an article written by a regular physician, who claimed that he had used carbolic acid pure in the treatment of burns with the result that pain was almost instantly relieved and an early cure effected. This statement somewhat astonished me and I admit that I was very skeptical on the subject for the following reasons.

Carbolic acid is, as we all know, a powerful escharotic and corrosive poison and acts as a strong caustic upon animal and vegetable tissues, even a weak solution of it destroying small animals. Its action upon man is analogous and when taken internally it irritates the gastro-intestinal canal, produces a feeling of intoxication, and turns urine an almost inky color. These phenomena are naturally most intense when a poisonous dose of acid has been taken and there may be added graver symptoms, such as delirium, dilated pupils, coma and death. I cannot imagine a worse suicidal medium than carbolic acid and still we hear of all sorts of people resorting to it as a means of suicide. This poison, I think, is frequently grasped at, because the public read so many sensational newspaper articles that they become convinced carbolic acid is a certain death when taken internally and because it is easily purchased without creating suspicion.[2] When undiluted the acid becomes caustic, as I said before, and may produce mummification of tissue; cases are on record in which the application of pure acid to a finger has caused strangulation and gangrene.

The best antidotes are albuminous liquids which are coagulated by the acid.

Externally carbolic acid acts as an escharotic when applied in the pure state, combining with the tissues and destroying them. Strange to say, however, its action on a burned surface as an escharotic is neutralized by the albuminous effusion becoming coagulated and local anesthesia of the peripheral nerves takes place. This looks like "similia similibus curantur." Its action in a dilute form when applied externally in promoting the cicatrization of wounds not burns is readily understood without the necessity of invoking its antiseptic qualities, for like many allied substances it operates as a stimulant to the parts to which it is applied, contracting and hardening them, while it protects them from the action of

[1] Read before the State of Missouri Medical Association.

[2] I suppose that, when these subjects reach the point where self-destruction is sought, the physical torture which carbolic acid produces is not taken into consideration. Death in such cases is not the direct result of the corrosive action alone upon the mucous membranes, but of the corrosion and paralysis of the epiglottis and subsequent rapid strangulation, the direct cause of death, then, being strangulation.

the atmosphere and thereby limits those secretions which tend to delay the healing process, while it favors the natural granulation or healing process through which alone new tissue can be formed.

The general result in burns treated with carbolic acid is that there is complete exclusion of air and coagulation of the serous effusions, and the healing process takes place with much less suffering and in a shorter time than by any other method which I have tried. We, of course, understand that carbolic-acid poisoning by absorption may result in some surgical cases when employed in too dilute a form, although in my practice during the last sixteen years and my hospital experience before I have been a strong advocate of carbolic acid in all cases where antisepsis in surgery or gynecology was necessary, I have failed to see one single case of poisoning from its use. Ever since the introduction of carbolic acid into surgery it has been assumed that it owed its advantages exclusively to its antiseptic virtues, but as I said before the exclusion of air is a very essential part in all antiseptic dressings for this prevents the entrance of microbes.

We often see in surgery where a laparotomy is undertaken that the surgeon, if in doubt as to the cleanliness and possible lodging of germs in the interstices of the epidermis, will resort to bathing the hands in pure carbolic acid, but immediately after washing it off with alcohol, the alcohol neutralizing the action of the acid.

There are a great many physicians who set aside carbolic acid as old-fashioned and instead employ bichloride of mercury as an antiseptic in obstetrics. The bichloride tablets are carried in the buggy case and no doubt are very handy, but in my experience with obstetrical and gynecological cases carbolic acid has been especially effective where septic infection has taken place, fever usually about the third to fifth day, rapidly subsiding after a thorough flushing with a strong solution of carbolic acid; by which the source of infection has been effectually sealed and further damage was prevented. I commend it especially in obstetrical cases after a forceps delivery, if the parts have been more or less bruised.

It is not necessary to go into details of the affections in which carbolic acid is used and in which its antiseptic qualities in a dilute form are inferior to bichloride of mercury. I will therefore proceed to give my experience with its use in the treatment of burns.

As previously stated, several years ago I had read the article on carbolic acid in burns and determined at the next opportunity to test the efficacy of this remedy. It seemed to me like homeopathy and in fact is an instance of "similia similibus curantur," although the "homeops" cannot claim any priority of discovery. The opportunity to test it soon came. I had burned my fingers severely on a bicycle lamp which I was admiring (but my admiration ceased at once), and not being very far from my office, made a bee-line towards it. I applied the much-lauded carbolic acid pure and to my surprise the pain ceased almost within ten seconds; there remained no further inconvenience except a feeling of constriction around the burned surfaces. I anxiously awaited the results and they were as follows: No blisters, swelling nor inflammation; the corroded skin came off in a few days, leaving a new skin and causing absolutely no inconvenience or pain at any time after the application. I did not even bandage the fingers, the surface where the acid had been applied acting as a protective callus. This being a small surface, however, I was not yet satisfied.

The next case which I was called to was a girl, twelve years of age, who had collided in the doorway with her mother; the mother was carrying a pail of boiling water, the contents of which were thrown over the little girl's chest, neck and shoulders. This was a case in which an extensive area had been scalded and I was rather timid in applying the carbolic acid. I did so, however, and immediately applied a vaseline dressing over the chest, neck, shoulders and face where burned, as my experience in my own case did not yet convince me of the efficacy of carbolic acid in burns on a larger area. To my great satisfaction and that of the girl the pain ceased within a few minutes and the case went on to recovery, without a single sign of a scar or contraction of the muscles of the neck.

The next case is a most interesting one in as much as I was one of the unfortunate occupants of a gasoline launch in which an explosion of gasoline took place. Mr. A. A. T. of our city had purchased for himself and friends a beautiful gasoline launch and in order to initiate his friends into the mysteries of gasoline boating on the Gasconade River, invited a number of them, with myself, to participate in a hunting and fishing excursion. Suffice it to say that we were all "on deck" when the time arrived to leave and reached our destination in due time. The gasoline engine, however, had become balky and Mr. T. and myself, as "expert engineers," concluded the fault lay in the quality of gasoline and proceeded after landing, to empty out the old gasoline to replenish same with new and better. Pardon me for telling this little story and I do it only in order that any suspicion of carelessness on my part will be eliminated from your minds. We were letting the gasoline run into the large pan under the engine and from there pumping it with a hand pump into the river; while I was stooping in the stern of the boat, Mr. T., who had warned all present not to come near with a fire, inadvertently made a connection with the electric-spark apparatus which ignited the gasoline vapor in the air and the next instant the boat, or rather the gasoline tank, blew up. I conceived in an instant what had taken place and had presence of mind enough to throw myself overboard into the river and into fifteen feet of water, the bank where we landed being so precipitous that it was impossible to get ashore quickly.

Mr. T., however, tried the shore route first, could not succeed in getting out of the boat, and finally followed my example and jumped overboard. Now, the river was all on fire as it were, the gasoline having been thrown upon it without a breath of air stirring and had remained where thrown. When I made my first appearance on the surface after my eventful dive, I came into a veritable hell of fire, and thought of the proverb "absence of body is better than presence of mind"; I did not stay long, you may imagine, but immediately made another dive and swam to shore under water, where I was drawn out unscathed and up the bank by some of our friends on shore.

Mr. T. did not fare so well. He was horribly burned; his entire head, face, neck and hands being one burn, the prominences as nose, chin and ears having been burned most severely, also the hands from which the skin hung in shreds. We left in a skiff at once for the station, only a few miles away, during which time Mr. T. suffered intensely. When we arrived at a physician's office I called for "pure carbolic acid." To the old M.D.'s surprise and consternation I vigorously applied the same to Mr. T.'s face, neck and hands, although at the time I considered the treatment rather heroic. I will state here that I also gave him a hypodermic of a quarter of a grain of morphine for the purpose of counteracting nervous shock, with the result that the pain from which he had been suffering intensely before ceased in about five minutes. We hired three oarsmen to row us to Hermann, Missouri, about five miles distant, where with the assistance of Dr. Brockhausen, I applied vaseline over the entire head, face and hands. The patient recovered without a single scar, although there was some sloughing on the end of the nose and rim of the ears.

I have since used carbolic acid on small burns in my family and elsewhere with the same result, but the above case is the most extensive burn upon which I have applied it.

INERTNESS OF PETROLEUM COMPOUNDS WHEN GIVEN MEDICINALLY.[1]

BY ROBERT REYBURN, A.M., M.D.,
OF WASHINGTON, D. C.;
PROFESSOR OF PHYSIOLOGY AND HYGIENE, MEDICAL DEPARTMENT, HOWARD UNIVERSITY.

WHEN we consider the chemical history and properties of the derivatives of petroleum and the more solid portion usually called paraffin, we are struck with their indifference to the action of strong acids and alkalies that usually destroy or combine with organic bodies.

The name paraffin (*parum affinis,* without affinity) is derived in fact from the character. Paraffins are not easily acted on by the strongest chemicals. Boiling hydrochloric acid or contact with chlorine gas, ammonia, potash or soda has no effect upon paraffin. By continued boiling with strong nitric acid, the higher paraffins yield nitro-compounds and various acids.

In view of the above facts it becomes an interesting study to determine to what extent petrolatum, when taken internally, can be absorbed into the body and its value as a medicinal agent.

It is universally admitted that fats of all kinds, when taken into the human stomach, are absorbed by the process of emulsification. This takes place by the action upon them of the alkaline fluids of the small intestine and pancreas. Cod-liver oil, for instance, is preferably given two hours after meals, for the reason that at that time the process of stomach digestion by the acid gastric juice is then nearly completed. The oil then passes nearly unchanged from the stomach into the small intestine, where it is emulsified and is absorbed into the lacteal system.

The wonderfully restorative effects of cod-liver oil in cases of tuberculosis and, indeed, in almost all conditions of the system which are attended with defective or impaired nutrition, has given it an importance and value far above any other medicine in the treatment of these cases. The disagreeable taste and odor of cod-liver oil are, however, great obstacles to its use, and some persons (though fortunately these are few in number) cannot take it at all. Other oils of less disagreeable flavor have been recommended as substitutes for cod-liver oil and among these the derivatives of petroleum have been largely prescribed and used.

The first question to be decided is, Are the compounds of petroleum, when taken internally, absorbed and made part of the tissues of the body in the same manner as, we know from the long experience of numerous observers, is the case when our patients take cod-liver oil?

An interesting series of observations on this point is given in a monograph on "The Behavior of Petrolatum in the Digestive Tract," issued by Drs. N. A. Randolph and Samuel G. Dixon in 1885, setting forth the result of their investigations in the Physiological Laboratory of the University of Pennsylvania. The following is an extract:

"The mixture of hydrocarbons, recognized by the pharmacist under the name of petrolatum, and popularly used under the commercial names of cosmoline or vaseline, presents on superficial inspection few points of difference from some of the organic fats of the same consistency. Close examination reveals differences, both in physical properties and in chemical constitution, between the bodies just compared. One point of difference, which I have as yet been unable to find recorded, lies in the respective behavior of these two groups when in contact with the absorbent surfaces of the digestive tract. Thus, while the organic fats as ordinarily taken in food are readily and almost completely absorbed, this soft paraffin is entirely rejected and found unchanged in the feces. During the eight days I took daily one-half ounce of commercial vaseline in addition to my regular diet. Digestion was in nowise altered, and no appreciable results ensued. Later, two healthy adults each received in the course of forty-eight hours one ounce of vase-

[1] Read before the American Therapeutic Society.

line. Their alvine dejections for three days from the beginning of this observation were collected and dried, and, at the suggestion of Dr. John Marshall of the University of Pennsylvania, extracted with petroleum ether. Making a slight allowance for incompleteness in extraction, the vaseline ingested was in each case recovered in its totality, showing that it had passed through the economy unchanged and unabsorbed."

Pure petrolatum, while entirely unirritating to the digestive tract, is valueless as a foodstuff.

Dr. Hutchinson in a paper published in the *Philadelphia Medical Journal,* April 15, 1899, p. 813, relates a similar experience with petroleum emulsion or rather petrolatum. In one case he gave 7 grams and recovered from the feces 7.1 grams, and in another case he gave 21 grams and recovered from the feces 21.6 grams. The increase of the amount of fatty matter found over the amount administered is probably to be accounted for by the solvents used having dissolved some of the fat which had been taken as food, and which had remained unassimilated in the intestinal canal. Dr. Hutchinson's final conclusion is that the compounds of petroleum or rather petrolatum are not absorbed.

My own experience also with petrolatum when given internally is that it passes unchanged through the intestinal canal. Whatever beneficial effects it may exert in the stomach and intestine are due to its lubricating and demulcent properties. A further incidental proof of the non-absorbability of paraffin and its compounds is shown by our recent experience in its attempted use in surgery. After certain surgical operations which involve great destruction of tissue, great gaps are left in certain parts of the body after the wound has healed. This is especially the case after the extensive mutilations which are necessary for the removal of cancers and other malignant tumors. It has been suggested that the appearance of these parts could be greatly improved by injecting paraffin in a melted state under the skin in order to prevent the adhesion of the skin flaps to the subjacent tissues and thus diminish the deformity. This has been done successfully in a number of cases, but, unfortunately, it was found that dangerous and even fatal results were produced by the paraffin wandering from the point where it was injected and closing up the lymph channels of the part. A reference to this danger will be found in the Medical News, April 20, 1901, p. 624.

Finally, therefore, if we consider (1) the entire insolubility of petrolatum and its compounds in either the gastric juice or the fluid of the intestinal canal, and (2) the fact that when petrolatum is given internally the whole of it can be recovered from the feces, we are warranted in stating that petrolatum can in no sense be considered a substitute for cod-liver oil as a nutrient and restorative, and (3) that the usefulness of petrolatum as a remedy must depend upon its unirritating and demulcent properties.

STRANGULATED HERNIA OF THE BLADDER; RUPTURED SARCOMA OF THE TESTIS MISTAKEN FOR STRANGULATED HERNIA.

BY THOMAS H. MANLEY, M.D., PH.D.,

OF NEW YORK

Extrusion of the bladder walls as a lesion coincident with reducible hernia is not very uncommon; it is very much more frequent than is generally supposed. Three cases of it have come under my own observation.

On this topic a recent writer[1] says the relative infrequency of hernia of the bladder may be appreciated by reference to Moynihan's table[2] which includes 187 cases. This analysis is based upon Bruner's report, which was published in 1889 and includes 38 cases. Other observers have made similar observations, Siegel collecting 73 cases in 1891 and Fenger adding 14 in his report of 1895, making a total in his collection of 87 cases.

It is a matter of general observation that the comparative number of hernias involving the bladder as a complication has increased since the publication of Bassini's method. The reason for this may be ascribed not only to the fact that operations are done more frequently now than formerly, but because the neck of the sac is exposed more clearly by the technic which has been uniformly followed since 1890.

Further insight into the frequency of this condition may be had by an analysis of the 2,500 operative cases[3] in the hands of eight experienced operators, which reveals 23, or nearly one per cent., in which the bladder was recognized as a part of the hernia, and yet, in approximately 700 operations Dr. Coley has not encountered a single case wherein the bladder was associated with the hernia. Dr. W. O. Roberts of Louisville, Ky.,[4] recently added another case which was successfully operated upon, the diagnosis having been made before the bladder was opened.

It has been said that any organ of the abdomen except the liver may find lodgment in a hernial sac, and in the fetal type of congenital exomphocele we may even find this organ enclosed.

From the histories of recorded cases, it does not appear that there are any special characteristic symptoms of vesical hernia, or that its presence as a complication is a source of special discomfort.

While vesical ectopia has long since been noted as an occasional accompaniment of groin and crural herniæ, I have been unable to find any cases recorded in which the condition has been present as a dominant factor in the strangulated variety; certainly none in which a distended, trapped vesical diverticulum has given rise to all the symptoms of strangulation and presented all the physical characters, as in the following case:

Mrs. G., eighty-two years of age; a housewife;

[1] "Hernia of the Bladder," by Charles C. Allison, M.D., Omaha, Neb. West. Med Review, March 15, 1901.
[2] Lancet March 2, 1900.
[3] Lancet, March, 1900.
[4] American Practitioner and News, Dec., 1900.

mother of fourteen children; a hardy, vigorous individual; throughout life has enjoyed fairly good health. During the past four years she has noticed a swelling in her right groin, low down; it was sometimes large, then smaller, and again, it would altogether disappear. She believed it was larger when she was constipated and it troubled her more in winter than in summer.

Throughout February, 1901, it became sensitive, permanent and larger, and at times, painful. On February 25th, she was seized with severe colicky pains all over the abdomen, particularly over the site of the tumor. Her physician came, tried taxis on the tumor and gave her some soothing remedies. She remained about the same on February 26th. At noon on February 27th her symptoms became more urgent and vomiting began. She showed signs of great weakness. Her abdomen had become tense and tympanitic. Taxis on the tumor had been repeatedly tried with no reduction.

On the evening of this date the case was first seen by me. Her general condition then was not as grave as might be expected, from strangulation of three days' standing in one so advanced in years. Her pulse was feeble, but regular, and the extremities were warm, and, though well under the narcosis of morphine, she was fully conscious. She frequently vomited a yellowish fluid without fecal odor. After an enema in the morning she had a free movement. The tongue was moist with red border. Thirst was not very urgent. The abdomen was somewhat tympanitic and sensitive. The lower limbs were drawn up. She had spells of great pain beginning over the site of the tumor. On the inner side of the right thigh, over Scarpa's triangle, a movable mass, about the size of an English walnut, could be defined. This was so sensitive that any pressure on it gave pain. On percussion it emitted a flat note. On inquiry about the urine it was said that she passed it unaided herself.

It was my opinion that the case was one of sub-acute strangulation and that the only effective mode of relief would be through an operation. This was opposed by the family until further efforts at reduction were made. She was then given chloroform and moderate taxis again tried. From the consistence of the tumor it impressed me as being an epiplocele, though I knew well from experience how deceptive the palpable characters of strangulated hernia are. Taxis failed. Three hours later preparations for a laparokelotomy were made. Everything also was in readiness to deal with a gangrenous intestine if it came in view.

Chloroform was again employed and I was ably assisted by Dr. L. Zwisohn, the patient's physician. With three assistants the operation was done in the patient's own apartments, the usual aseptic precautions being observed. The first incision was made from above downward over a distance of six inches, the center passing over the convexity of the tumor. Successively the various layers were divided at the neck of the sac until Gimbernat's ligament was reached and the crural ring exposed. Then the inner border of the ring was freely opened and with it an adherent branch of the obturator artery was cut in two. The ends of this were picked up and ligated.

It was my purpose to expose the peritoneal pouch, but as I dissected through the investments it appeared that the peritoneum had undergone changes and become adherent to all the adjacent parts. Moreover, the distention of the sac had now entirely disappeared. This puzzled me and for the first time it dawned on me that this might be a case of hernia of the bladder; in spite of the fact that before operation she had been catheterized and six ounces of urine removed.

After a careful manipulation of the parts it seemed to me that we were dealing with only a thickened sac, and that its contents had been returned to the abdomen on the division of Gimbernat's ligament. It was then completely divided with the end of the scissors. Immediately a straw-colored, limpid fluid escaped, much the color of the peritoneal secretion, but being in doubt I introduced into the sac my index finger and it came into immediate contact with a catheter passed through the urethra.

The breach in the bladder was closed by two rows of fine silk suture, the closed wound being firmly secured at the inner margin of the incision in order to provide for possible leakage from the vesical wall. On the outer margin of the bladder a small omental mass was found; this was firmly adherent to all the adjacent parts. It was devoid of a peritoneal investment. It was ligated and cut away. The upper end of the incision was closed, but the lower kept freely open by packing.

The after-history of this case was very satisfactory. The vesical wound healed by primary union with no leakage whatever, but for two weeks after the operation she was troubled with cystitis.

Such is the history of this unusual type of hernia. Without an ocular demonstration we would certainly be disposed to doubt the possibility of a vesical extrusion provoking all the symptoms of strangulation. Here we had a vesical diverticulum slipping out through the crural ring, becoming distended and in time provoking inflammation at the point of constriction, the pent-up, decomposing urine producing excessive irritation with reflex pain over the entire abdomen. This was, anatomically, an example of extraperitoneal vesical hernia of the bladder walls, the parts being projected from below the peritoneal reflection, through the space of Retzius.

Operative Technic.—In the recent past the largest factor in swelling the mortality list after operation has been faulty, defective operative technic. Gibbons sets down 15 per cent. as the proportion of deaths from this cause alone. It is my conviction that fifty per cent. would be nearer the figure.

Briefly the fundamental features in technic may be enumerated under the following heads: (1)

A large incision involving a laparotomy; (2) free division of the constriction from *without* in; (3) the deliberate, methodical and complete treatment of any important complication then and there.

The lives of a large number of those with strangulated hernia are sacrificed by the violence involved in being transferred to hospital; hence, in any other than very exceptional cases, they should be treated *sur le champ*. Let no one allow himself to be intimidated by the phantom of infection, for no hospital ever constructed will provide results equal to a clean, comfortable, orderly household.

The second case is that of a Russian peddler, aged forty-one years, brought to the hospital at midnight, May 21, 1901, in the ambulance, having been seized with symptoms of strangulation early in the evening. A physician who had been called in perseveringly tried taxis, but without success and sent the patient to the hospital. I saw the man an hour after his admission. He was vomiting freely, was very anemic, very weak, and constantly groaning with pain. The abdomen was distended and highly sensitive everywhere. On the right side, extending from the inner inguinal ring to the scrotum, was a large tumor. The scrotum was greatly distended and showed signs of severe bruising by the taxis which had been employed. The mass presented many of the common characteristics of a hernial protrusion; it was continuous with the inguinal canal and seemed to contain a fluctuating substance, solid on percussion. The patient stated that he had had a rupture for five years and had worn a truss the greater part of that time, although it never kept the hernia well up. His bowels had not moved for three days. His features were pinched and showed the signs of severe pain. His pulse was 136; temperature, 97° F. The history and clinical picture of the case pointed to strangulation and operation was indicated.

The patient was anesthetized and an incision, beginning two inches above the internal ring and carried down nearly to the base of the scrotum, was made. On division of the tendon of the external oblique it was at once clear that the spermatic cord was the seat of a new growth which greatly distended the infundibular fascia and extended down to and well into the testicle. The tunica vaginalis was widely ruptured on its anterior aspect and through it projected a large, fungoid, bleeding mass. The tumor of the testis and cord was enucleated, the vas deferens and vascular stems of the cord being divided and ligated at the inner ring. There was no trace of any description of hernia. The rupture of the tunica vaginalis probably was caused by forcible taxis.

The two foregoing cases are thought worthy of record as illustrative of the difficulties which not infrequently beset surgical diagnosis in the treatment of various phases of hernia and allied conditions.

MEDICAL PROGRESS.

Bacterial Products and Peripheral Nerves.—The relation of bacterial poisons and the peripheral nerves has always been of interest. DRS. DOPLER and LAFFORQUE (*Arch. de Méd. Experimentale*, July, 1901) have investigated this subject by the experimental inoculation of a large number of such substances. They employed diphtheria toxin, tuberculin, bacillus pyocyaneus, streptococcus, staphylococcus, pneumococcus, pneumobacillus and cholera and pest toxins. Soluble products of the colon bacillus gave practically no results. These various substances were inoculated locally around the peripheral nerves of guinea-pigs. Account was taken of the clinical symptoms produced and a microscopical examination of the nerves was made. They believe that inflammations of the peripheral nerves of infectious origin are due to the action of bacterial substances circulating in the peripheral blood-vessels. These penetrate by dialysis into the interior of the nerve fiber at its most vulnerable point, the nodes of Ranvier. They exert a necrosive chemical action on the elements of the interannular segment sometimes the axis-cylinder being relatively more affected than the other parts. The entire picture resembles a peri-axillar segmentary necrosis. If the axis-cylinder submits to grave alterations rupture and fatal degeneration follow, accompanied by the characteristic symptomatic conditions.

Chemical Reaction and Power of Bactericidal Serum.—As the mode of action of bactericide serum has been compared to that of a proteolytic enzyme, the question is raised whether the chemical reaction of the surrounding medium can influence the bactericidal power. A. HEGELER (*Arch. für Hygiene*, Vol. 40, Heft. 4) has pursued investigations along these lines. His work was confined to the use of antityphoid sera on rabbits. He added acid or alkali to such sera and showed that active rabbit antityphoid serum was not changed in its bactericidal power by the addition of a very small amount of alkali (sodium carbonate). The smallest addition of such alkali, however, to inactive serum caused it to hinder the growth of typhoid bacilli. Small additions of acid, just sufficient to produce a very slight acid reaction to active rabbit serum, did not alter its bactericidal power, but when the reaction was made decidedly acid the alexins of the serum entirely lost such power. Careful observations have shown that the reduction in the number of bacilli in the sera was genuine and not due to an agglutination process.

Growing Vegetables Contaminated by Pathogenic Microbes.—This subject has been exhaustively investigated along experimental lines by R. WURTZ *and* H. BOURGES (*Arch. de Méd. Experimentale*, July, 1901). The first series of experiments was carried on in the laboratory. They took pots of earth in which were planted various vegetables and thoroughly saturated the earth with water containing cultures of anthrax,

typhoid and tubercle bacilli respectively. After variable periods of time search was made upon the leaves for the presence of these organisms. Ordinary "plate" methods were not available, as there was too much contamination by the ordinary earth organisms. In working with the anthrax bacillus they heated these leaves for three minutes to 80° C. and then made gelatin plates from them. With the typhoid bacillus the leaves were placed in carbol-broth and incubated at 42° C. for two hours; platings in gelatin were then made and the organisms recovered, after which they were identified by the agglutination test. With the tubercle bacillus an emulsion of the leaves in sterile broth was inoculated intraperitoneally into guinea-pigs. By these methods they recovered the anthrax and typhoid bacilli in every case for three weeks following the inauguration of the experiments. In one series they recovered the tubericle bacillus once out of four times and in another series eighteen out of thirty times. In another set of experiments they contaminated vegetables under domestic cultivation with non-pathogenic organisms. These were frequently watered, some being protected from the sun, while others were not. Those which were protected always showed the presence on their leaves of the organisms sought, while in those which were not protected these organisms were never recovered. They contaminated potatoes with virulent anthrax bacilli and planted them in boxes of earth. Upon sprouting these were exposed to the sun for three hours daily. The anthrax bacillus was recovered from the leaves of the developed plants 41, 93, and 101 days after planting, but these organisms had lost their virulency. They conclude that, although the bactericidal action of the sun's rays plays an important part in destroying micro-organisms, infection is possible from eating uncooked vegetables and all possible precautions should be taken against contamination of the soil in which they are cultivated.

Immunity in Relapsing Fever.—The study of the mode of action of the specific serum on the spirillum of relapsing fever both *in vitrio* and in the animal organism, the investigation of the mode of disappearance of these spirilla in the bodies of refractory animals, and the relation between the bactericidal substances and leucocytosis in those sick with this disease have of late occupied the attention of different observers. The most recent work along these lines comes from SAWTSCHENKO and MELKICH (*Annales de L'Institut Pasteur,* July 25, 1901). Their investigations were made during the epidemic of Kansan in the winter of 1900. Their observations included the study of the relation of the spirillum to the phenomena of Pfeiffer and agglutination, together with experimental research with respect to the action of the spirillum in normal and immunized animals. Furthermore, they investigated the condition of leucocytosis in individuals with this disease. They find in the blood of relapsing-fever patients two substances which have a special affinity for the spirilla, namely, (1) agglutinine and (2) immunizing substances (fixatives). These latter result from the intracellular metabolism of the spirilla and when they combine with the alexins of the serum occasion the destruction of the spirilli *in vitrio.* These appearances are analagous to the phenomena of Pfeiffer. The extracellular destruction of the spirilla takes place in certain regions of the body, such as the peritoneal cavity, of an immunized animal where the alexins and fixatives combine but it does not occur in the plasma as the alexines are not here present in a free state. In fifty cases where the blood examination was made before the crisis they never found the detritus of spirilla or those altered after the phenomena of Pfeiffer. If there is not free alexin present in the regions of the body mentioned the spirilla disappear by phagocytosis. The fixatives serve intermediately between the spirilla and the leucocytes transforming a negative into a positive chemiotaxis. The phagocytotic crisis is determined by the accumulation in the organism of the fixatives, be they in the leucocytes or in the bodies of the spirilla, and contribute undoubtedly to the formation of agglutinines.

Notes from the Children's Ward.—The following is the substance of a clinical lecture by A. JACOBI (*Medicine,* Aug., 1901). Case I.: Tuberculous peritonitis. A cure may result spontaneously and is facilitated by rest in bed and the use of guaiacol and iodide of potash. Cod-liver oil and good food should be given, ascites removed, and if these measures fail, a laparotomy should be performed. Case II.: A boy with headache, frowning, delirium, rigidity of the neck, and enlarged pupils that do not contract. One symptom of cerebrospinal meningitis, Trousseau's, is absent. This is the anemia followed by hyperemia on drawing the finger over the skin. In this case acute rheumatism must be thought of, and salicylates administered, for many such cases are taken to be meningitis. Case III.: Endomyocarditis in which strychnine failed to produce improvement, but when it was stopped and opium given in its place, the child improved. Codeine sometimes acts well in such cases. In a chronic heart trouble have the patient take digitalis and go to bed and rest a month or two, and at the end of this time renew the digitalis.

Syphilis of the Liver.—Following a discussion of the literature on syphilitic disease of the liver, MAX EINHORN (*Med. Rec.,* Aug. 17, 1901) classifies the tertiary lesions into gummata and cirrhosis, and either of these accompanied by acute or chronic icterus. Most cases have pains in the right hypochondrium, either constant or in attacks which may resemble gall-stone colic. There may be lack of appetite, frequent eructations, bad taste in the mouth, and constipation, or more rarely diarrhea. General malaise, restless sleep, moroseness, weakness and loss of weight are often present, but the emaciation is never so great as that of cancer. Acute icterus may be catarrhal, or due to temporary compres-

sion of the duct by a gumma. In chronic icterus, the duct is narrowed by gummatous tumors or scar tissue, or is involved by the connective tissue proliferation. The liver is usually swollen and uneven, round and hard nodules may sometimes be felt on its surface. In the more advanced stages amyloid degeneration appears. Enlargement of the spleen is frequent, but not constant; ascites may develop. The diagnosis cannot be made with certainty, for syphilitic cirrhosis resembles ordinary hypertrophic cirrhosis, but with a history of lues, and nodules in an enlarged liver, the diagnosis is probable and may be confirmed by antisyphilitic treatment. Iodide of potassium sometimes benefits an ordinary hypertrophic cirrhosis, though to a less extent. If nodules have lasted a year or two without marked loss of weight, it is probably syphilis and not cancer. Neusser believes that an increase of eosinophiles in the blood points to syphilis. An alcoholic gastritis accompanying a uniformly enlarged liver, argues for alcoholic cirrhosis. The prognosis is favorable if treatment is instituted before ascites, albuminuria, etc., have set in. The best results come from the combined use of inunctions of mercury and iodides internally; but anemia requires iron or arsenic, ascites requires puncture, and icterus may be reduced by glycerin, gm. 4.0 (3i) t.i.d., half an hour before meals. Alcohol must be forbidden, and proper diet and hygiene insisted upon.

Blastomycetes in the Tonsils.—The relation of the blastomycetes to abnormal tonsillar conditions has recently been investigated by E. Bertarelli and N. Calamida (*Ctlblt. f. Bäk.*, July 18, 1901) who examined the tonsils of patients in otological clinics. They studied fifty tonsils of which twelve were normal and the remaining hypertrophied. In their work they employed greatly diversified culture media, as agar, potato-agar, gelatin of different reactions, and glucose and ordinary bouillon. The media yielding the best results were those of Casagrandi and some prepared from the juice of different fruits and agar. Some of these cultures were kept at incubator and others at room temperatures. They also studied tonsillar sections. From all their cases they were only able in four to isolate these organisms, none of which were pathogenic for guinea-pigs, save one in which the result was doubtful. In histological and pathological sections they were constantly found. They think that such finds do not explain the pathological conditions of hypertrophied tonsils and that it is very probable that they are only degenerative forms of these organisms whose presence is accidental and is of no significance.

Pregnancy Following Myomectomy.—Fourteen cases have been reported, with eighteen pregnancies, and nine healthy children born at term, writes J. N. West (*Med. Rec.*, Aug. 17, 1901). There were two stillbirths at term and six abortions, most at the third or fourth month. All these uteri had extensive scars from the enucleation of tumors, but all had normal presentation, normal positions, and in only two were forceps necessary. In two cases gestation was complicated by a flow of blood or amniotic fluid from utero-abdominal fistulæ, which remained at the site of operation, but healthy children were born.

Agglutination of Bacteria.—The contention of Emmerich and Loew, that bacterial agglutination, particularly as applied to the bacillus pyocyaneus, and the sedimentation seen in old bouillon cultures are identical phenomena and dependent upon enzyme formation, has been strongly disputed. The most recent contribution to this subject is made by P. T. Muller (*Ctlblt. f. Bäk.*, July 18, 1901). He employed ten-day-old bouillon cultures of this organism obtained from two different sources. These contained an abundant deposit of organisms and also a large quantity of enzyme. The microscopical examination of this sediment in dilutions of from 1 to 1 to 1 to 1,000 showed no trace of agglutination. By heating these cultures to 55°-60° C., and thus removing the enzymes, he was enabled to produce agglutination of the organisms when brought in contact with a specific serum. He, therefore, opposes the view of Emmerich and Loew and thinks that agglutination is produced by substances formed in the animal body exclusively.

Malaria in Honduras.—The propagation of malaria by the mosquito is now an accepted theory, but here, 4,000 feet above sea-level, and far above the mosquito belt, J. H. Egbert (*Med. Rec.*, Aug. 17, 1901) finds malaria of common occurrence. There is abundance of good water, excellent natural drainage and a salubrious climate. The author has been led to conclude, without microscopical investigation, however, that fleas are the agents which carry the infection. During the run of the fever, his treatment consists of quinine and acetanilid, with calomel or saline laxatives; for the subsequent disturbances he gives quinine and mineral acids, or Fowler's solution, with podophyllin or other hepatic stimulant.

New Technic for Seeking Bacillus Typhosus in Water.—Notwithstanding the great importance of water as a contaminating agent in typhoid infection the successful isolation of typhoid bacilli from drinking water is of comparatively rare occurrence. Gabriel Vallett (*Arch. de Méd. Experimentale*, July, 1901) points out that the chief obstacles are, first, the inability to examine a sufficient quantity of the water, and, second, the very frequent presence of the colon bacillus in such waters as contain the typhoid organism. The colon bacillus, by reason of its great vigor, survives the manipulations resorted to in most water tests, while the typhoid organism is destroyed. Particularly is this the case in the method of Péré in which passages through carbol-broth are employed as a part of the process. He recommends the use of the following new method: To 20 c.c. of the water are added four drops of a saturated, sterilized

solution of hyposulphite of soda and an equal quantity of a like solution of nitrate of lead. This forms a precipitate and clouds the liquid. Upon being centrifuged the supernatant fluid is poured off. Investigation has shown that this is practically sterile. The precipitate is then dissolved by a drop-by-drop addition of the soda solution. He then divides this in a series of tubes containing Elsner's potato-gelatin and "plates" in the ordinary way. Colon colonies develop in thirty-six hours, but typhoid often require three or four days. The organisms are then identified by the usual methods. This method has two advantages: (1) The examination of a considerable quantity of water; (2) the avoidance of any antiseptic action on the typhoid bacillus.

THERAPEUTIC HINTS.

Urticaria.—

℞ Menthol ..... gm. 0.10 (gr. iss)
Alcohol
Ether
Chloroform ..... aa 30.0 (℥i)

—Gaucher in *Bull. Gén. de Thérapeutique,* July 30, 1901.

Soothing-Draught.—

℞ Potass. bromid. .... gm. 2.0 (gr. xxx)
Spt. melissæ ..... 10.0 (℥iiss)
Syr. etheris ..... 30.0 (℥i)
Tinct. valerian..... gm. 3.0 (gtt. xl)
Aq. ad.... ..... 120.0 (℥iv)

—Brissemoret in *Bull. Gén. de Thérapeutique,* July 30, 1901.

Anemia.—A teaspoonful of the following mixture is administered four times a day:

℞ Euquinine ....gm. 4.0 (℥i)
Ferri lactat. ..... 8.0 (℥ij)
Liq. acidi arsenosi .... 6.0 (℥iss)
Tr. lavand. comp. ..... 15.0 (℥ss)
Elix. aurantii, ad. .....120.0 (℥iv)

If considered desirable, strychnine sulphate may be added.—Blackwood.

Pambotano.—This is a leguminous plant of Mexico, Senegal and Gabon, employed in malaria, typhoid, influenza, and other fevers as a succedoneum for quinine or cinchona. It is used in decoction, cc. 500.0 (Oj) of which may be taken in small doses during the day.—Callandria in *Bull. Gén. de Thérapeutique,* July 30, 1901.

Bronchitis with Asthma.—In children a few doses of the following are usually sufficient to relieve the dyspnea until another attack of bronchitis supervenes.

℞ Potass. iodid ..... gm. 4.0 (℥i)
Liq. ammon. anisat. ... 2.0 (℥ss)
Syrupi ..... 2.0 (℥ss)
Aquæ q. s. ad. ..... 90.0 (℥iij)

M. Dose, one teaspoonful every four hours.—A. Caillé in *Pediatrics,* Aug. 15, 1901.

Pericarditis with Effusion.—When accompanied by rheumatic polyarthritis, the etiology is evident, and we give the nearest to a specific, *viz.:*

℞ Sodii salicyl. ... gm. 0.3 (gr. v)
Potass. iodid. ..... 0.12 (gr. ij)

Sig: Four times a day in water.

At the same time order rest in bed, a daily warm bath and fluid diet, and as soon as removal is safe, give the patient sunshiny country air.—August Caillé in *Pediatrics,* Aug. 15, 1901.

Spinal Anesthesia.—The indications are advanced age, cachexia, pulmonary or renal disease, fear of general anesthesia on the part of the patient, simple operations on the lower limbs not suitable for local anesthesia, and in cases where one is without an assistant to administer an anesthetic. The contra-indications are operations above the umbilical level on account of the inconstancy of the analgesia in this region, operations on the abdominal cavity on account of possible vomiting, and the frequent necessity of the Trendelenburg or other position unpleasant to the patient, operations requiring absolute muscular relaxation, youth and nervous fear of operation.—Vannerts in *Le Nord Médical,* Aug. 1, 1901.

Puerperal Infection.—Besides the usual symptoms of fever, rapid pulse, abdominal pain either spontaneous or provoked by palpation, changes in the lochia, etc., P. Budin (*L'Obstétrique,* July 15, 1901) recommends a digital examination of the interior of the uterus. In the normal uterus a few days after labor the internal os is firm and is penetrated with a certain effort. If, however, the uterine mucosa is diseased, it seems as if the muscular fibers were paralyzed, for one's finger is easily inserted into the cavity. One may also find there debris of clots, membranes or placenta, which give the finger a fetid odor. If the uterus contains only clots more or less odorous, and the uterine mucosa is smooth except at the placenta site, intra-uterine antiseptic injections will suffice. If the finger detects placenta or membranes, or if at the placental site pressure suffices to detach friable pieces, one should perform digital curettage followed by sponging. This curettage must be thorough, the bladder and rectum being emptied, and the abdominal wall relaxed under anesthesia. One or more fingers are inserted into the uterus, the outside hand holding the fundus, and the walls are scraped clean. Then an intra-uterine injection of bichloride, 1=4000, is given, and one or two sponges plunged in creosote-glycerin, 1-5, are inserted. Following this a vaginal douche prevents the caustic effect of the creosote on the vagina. If there is a noticeable bloody discharge, one or two tapes of iodoform gauze are introduced into the uterus for drainage. If the infection has lasted some time before this cleansing, the cure will be slow, and if the system is seriously invaded, active supporting treatment will also be necessary.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

HOSPITAL MANAGEMENT.

Among the Chicago items in the Medical News for August 17th and in this issue are two to the effect that the internes at the Cook County Hospital have been absolutely forbidden to perform any major operation or high-forceps delivery even in the presence of the attending surgeon. The rule covers all operations in which an anesthetic is employed. Figure to yourself, as the French say, Wier, McBurney, or Hartley summoned to the hospital because a pelvic examination of a nervous patient requires anesthesia, or because of her refusal to allow the opening of an abscess, or a painful dressing, without it! The statement that the internes are up in arms is hardly necessary as such is the inevitable result of so sweeping an order.

It is to be hoped that the natural outcome of such short-sighted policy may be avoided by some modification of the rule. No hospital can reasonably expect to secure as internes the best class of men if they are to be treated as absolutely irresponsible beings. Such a course may work temporary good to the patients, but in the end must yield results inferior to those which would be obtained by more moderate restrictions. That the interne is human, and often so anxious to secure an operation that he may occasionally leave some stone conveniently unturned in order to fail to secure the presence of the attending surgeon and thus accomplish his purpose, is not unnatural. And it has happened more than once that the patient has not profited by this circumstance. It is not necessary to leave this city to secure examples, nor is it difficult to find opportunities to study the cause and treatment of such a trouble.

Severity and sweeping restrictions inevitably result in insubordination and lack of interest of a house staff, frequently to dishonesty by evasive methods, and to eventual deterioration of the quality of men who are willing to fill the positions. The interne, presumably a man appointed after a fair competitive examination as the candidate best fitted for the position, is the servant of the hospital in return for the experience which it affords. In this position he is entitled to whatever knowledge he can secure without injury to its inmates, and absolute prohibition to perform major operations even in the presence of the attending surgeon robs him of his just dues. Furthermore, it turns out a prospective surgeon who will be obliged to secure his training by operating, without the advice and guidance of a more experienced man, upon what private patients may be unfortunate enough to fall into his hands. That the framers of unwisely restricted orders may learn their mistake by suffering by them is too much to hope.

No one can exert so strong a protective influence over the patients as the attending surgeon. There are few ex-internes in this city who have not learned that the higher the grade of work done by him the better will be that of his assistants, and that the man who is willing to respond to a call from them at any hour of day or night will be met more than half way. Furthermore it is not the attending surgeon who is generous to his assistants who loses the opportunity to perform an operation in which he is especially interested, through professed inability to locate him at the time. Not an interne but knows why a certain division is always chosen first when the operator upon another may be of equal skill. Nor is the surgeon who neglects his service and telephones to operate without him the most successful in securing the coöperation of his staff. On the other hand, one who considers that his assistants will learn more by watching him may be right in the early part of their course, if his

estimate of his own ability is correct, but a subsequent operation performed merely under his guidance is of infinitely more value than the privilege of being again an onlooker. The surgeon who will sacrifice himself by giving such personal instruction will lose nothing either in the quality and willingness of the service of his assistants or in their lifelong regard for himself and his professional ability. The hospital which rules its internes in this way is to be congratulated upon its sagacity and good fortune. And this is as true in New York as in Chicago.

BLOOD ALKALINITY AND MEDICATION.

One of the most striking things about the chemism of the human body, so far as we know it, is the uniformity of its processes despite the many and ever-varying factors that enter into it. The physics of the body involve practically the same mysteries, but we have become more familiar with them and they fail to appeal to us so strikingly. The maintenance of the human temperature at a cyclic constant between 97.8° and 99.2° F. is a most intricate problem in heat conservation and heat dissipation. With the surrounding air at a temperature of -70° C., far below that at which alcohol solidifies, members of Polar exploration parties find their average daily temperature not below 98° F. Visitors to the tropics, under an equatorial heat at midday of over 120° F., do not find their temperatures in health above 99° F. The modifications of chemism necessary to maintain this constant temperature in the midst of external variations are extremely complicated, yet in spite of them the nutritional processes of the body remain undisturbed and are accomplished in just the same way as in the comparatively uniform temperature of the temperate zones.

With this consideration in mind it is not so paradoxical to find that the blood, despite alterations in metabolism, remains almost absolutely constant in certain of its qualities. Several years ago the English physiologist, Sir Michael Foster, pointed out that the alkalinity of the blood is one of its most uniform characteristics. The degree of blood alkalescence, for instance, cannot be changed by the administration of alkalies. Alkali substances which find their way into the circulation and which, if retained, would increase its alkalinity are promptly excreted by the kidneys. It has for many many years been a favorite therapeutic idea that the blood could be rendered more alkaline and thus certain diathetic conclusions dependent on the presence of frèe acid in the blood relieved. While the theory of an acid diathesis as the basis of rheumatism has not in recent years met with the favor it gained in a preceding generation, most physicians have been ready to concede that some form of acidemia was the groundwork of gout. Sir William Roberts refuses to admit even this, however, and deprecates utterly the value of alkaline treatment in gouty affections.

Dr. Henrich Stern at the last meeting of the New York County Medical Society still further added to the complications of the problem of increasing or diminishing blood alkalinity by reporting the result of a series of personal observations on the relation between blood alkalinity and urinary acidity. It has usually been assumed that an increase of the alkalinity of the blood decreased the acidity of the urine and *vice versa*. In Dr. Stern's experiments, however, variations in the alkalimetric curve of the blood by no means corresponded to analogous changes in the urine. It is possible to have increasing urinary acidity while blood alkalinity remains stationary or is even diminishing. Dr. Stern showed also that the alkalinity of the blood was not a function of dietary variations and that alterations in the comparative intake of proteid and carbohydrate foods had practically no effect.

The degree of blood alkalinity in any given subject is dependent to a large extent on the individual. Different individuals even when perfectly normal have distinctly different degrees of blood alkalinity, just as they have varying types of metabolism. In a word, instead of a simple problem, whose equation can be varied by affecting certain factors, the alkalinity of the blood is one of the most complex products in the human economy. It is probably very fortunate that we have not been able to effect it as easily by drugs as has been thought possible. Micro-organismal growth may be encouraged by even slight variations in the reactions of such media as the blood. It is as distinct a step in advance, however, to realize that we can affect the uniformity of blood alkalinity very little as it was for the generation before ours to realize the futility of specific medication. It is not the employment of specific drugs, but the care of the individual patient in the many details of his affection, that constitutes successful therapeutics. It is not the production of gross changes in the important circulating media, blood and lymph, that we can hope to employ for curative purposes. The problem of successful treatment for disease

or diathesis is never as simple as that crude notion would seem to imply. Therapeutics is, and must be of its very nature, essentially individual in character until we know something more definite about human chemism and the intricate factors that enter into it in health and disease.

SUBSTITUTION: A MEDICAL EVIL.

FROM the eagerness of the proprietors of patent medicines to call the attention of the public to their "blue label" or "white seal," or "signature without which none is genuine," we are led to believe that there must be a large number of people in this world who believe that imitation is the sincerest form of flattery, and who devote their whole lives to preparing something "just as good" for the consumer. It is a little startling to have our vague ideas corroborated, and to know that there are large manufacturing concerns that put up nothing but imitation medicines, drugs, flavoring extracts, everything from the synthetic oil that passes for orange phosphate in cheap soda-water fountains to the inactive scopolia root that is substituted for belladonna.

The manufacturers of proprietary articles are perfectly justified in their strenuous efforts to warn the public against such impostures, for it is not merely a question of another man pocketing the dollars that ought to recompense them for their advertising and labor, it is a question of reputation. Even a patent medicine has a standard of efficacy that must be maintained. But while its imitator runs the risk of law-suits, the second-rate druggist busies himself with inferior drugs, and cheap chemicals and no one seems to know the difference.

We physicians hardly realize that substitutions and adulterations are as diligently worked off on us and our patients as in the patent medicine field; that non-official leaves are ground up with official leaves, that tinctures are made from fluid extracts instead of from fresh drugs, and that old weather-beaten drugs are sold in the market for use in the preparation of potent remedies.

The high class pharmacists of the large cities are so wholly above reproach that we would depend on their testimony rather than on our own in deciding about the purity of the drugs used; but who of us whose prescriptions every day are filled up-town and down-town, in the suburbs and in neighboring cities, have any guarantee that they are filled in such a way that they will have the strength and potency that we in all good faith prescribe?

The United States Pharmacopœia is the official code which determines the strength of all preparations and on it the profession base their prescriptions, but it is a startling fact that although the last twenty years have been the most brilliant in research work in the physiological reaction of drugs, yet far too many pharmacists are using the Pharmacopœia of 1880, if they use any at all, the edition of 1890 not having as yet gotten past the minority.

We may not take the matter of substitutions quite as seriously as do our friends who dispense drugs under their signatures, but we certainly ought to treat it more seriously than we do; for our reputations as well as our patients will undoubtedly suffer. That we permit the state of affairs to exist at all is due to the very widespread carelessness mingled with the trustful ignorance with which we put our prescriptions in our patient's hands, not knowing where or how they will be filled.

ECHOES AND NEWS.

NEW YORK.

Brooklyn Eye and Ear Hospital.—The recent annual report of this institution shows that it is in a flourishing condition. During the past year there were treated 14,883 cases. Of these 9,199 were diseases of the eye; of the ear, 3,110; of the throat, nose and skin, 2,327; of the nervous system, 247. The total year's income was $16,000. The erection of a new hospital building is under contemplation.

Registration of Tenement Houses.—All property owners in Brooklyn have recently been notified that they must report their houses as tenements if they contain three or more families. A failure to do this will be punishable by a fifty-dollar fine. In order that no injustice may be done no fines will be imposed until after September 6, 1901.

PHILADELPHIA.

Invalid's Long Fast.—A rather remarkable case of fasting is reported from Emlenton. Mrs. Jane Lynn, who had been an invalid for years, died August 12th after taking absolutely nothing except an occasional glass of water for fifty-five days. During sixty-one days she had only one ounce of food.

Pest-House Torn Down.—The smallpox pest-house erected on the Bowen estate near Schuylkill Haven has been torn down by the heirs who say that permission to build had not been granted. The County Poor Directors settled the matter by giving a site for the proposed hospital.

Donation to York Hospital.—A citizen who wishes his name withheld has donated

$40,000 to the York Hospital, the money to be paid after his death.

Sentence of Malpractitioner Reduced.—Joseph Heppenstall alias "Dr. Heppe" or "Dr. Hill" was recently sentenced to four years in the penitentiary for causing the death of an infant by criminal malpractice, the infant dying six hours after its birth in the Philadelphia Hospital. Later the sentence was reduced to two years.

The Regulation of Hospitals.—The institution known as the "Prince of Peace Hospital" has lately been the subject of investigation by a Coroner's jury, the death of an infant being the subject of inquiry. Testimony revealed the fact that the institution has been in operation for two years without a license, although some patients in the lying-in department had been obtained by advertisement. At the last meeting of the Legislature an institution in the city asked for $40,000; inquiry revealed the fact that it had not even a resident physician. The condition of affairs is well expressed by the *Ledger,* which, in commenting upon the first case, says: "The incident fairly suggests the comment that has often been made heretofore, that numerous institutions of a charitable or semi-charitable character are organized, often by well-meaning persons, when there is no pressing public necessity for the institution, and which cannot be adequately supported without State aid. They belong to the class which the State Board of Charities designates as those which are controlled by individuals sometimes assisted by grants from the State.' There is reason to believe that many so-called charitable institutions have been founded not to meet a pressing and obvious need of the locality, but eventually to secure State aid for what may be called hospital promoters."

Physician Made Prominent by Strike.—Dr. Robert J. Black, Mayor of McKeesport, is probably the most talked-about physician in the United States at present, his proclamation regarding the participants in the steel strike being the subject of comment. Mayor Black has a rather unique and enviable history. For twenty-five years he has been practising medicine in McKeesport, but has accumulated no wealth because he is the "poor man's" doctor. He visits the worst sections of the city and no man is too poor to get him out of bed any hour of the night. Black fights the United States Steel Corporation and hence was bitterly antagonized by it and the politicians when he was running for mayor. The poor people of the town remembered his kindness and they elected him by a majority of one vote against all opposition.

CHICAGO.

To Analyze River Water.—To checkmate the secret investigations of St. Louis experts into the character of the water in the Chicago River, the Sanitary District Trustees have made plans for a new series of observations and analyses of river water. Four St. Louis chemists have worked two weeks on samples of water from the mouths of the sewers and are now moving down stream. The Trustees will follow them at every point and duplicate their former observations in order to prove, if necessary, that the water does not vary in quality with the seasons. Judge Springer of Washington, Attorney-General Hamlin, Special Counsel John J. Drennan, and Dr. Frank W. Reilly of the Health Department have met with the Trustees. St. Louis has spent $35,000 thus far for evidence and has $40,000 available still. The Drainage Board has only spent $18,000 on this line.

Epidemic in Evanston. It is said that Evanston has an epidemic of scarlet fever and diphtheria. Within the last few days fifteen new cases have been reported to the Health Department. Most of the cases are from the southern wards of the city. Health Commissioner Parkes is at a loss to account for the outbreak, but believes the epidemic was caused by children bathing in the lake near the mouths of the sewers, and he will take steps to prohibit all bathing in certain places.

Typhoid Fever and Malaria Prevalent.—It is said that these diseases are epidemic in the nineteenth ward. So general have these diseases become that the Nineteenth Ward Improvement Association has issued a warning bulletin on insanitary conditions. Visiting nurses from Hull House are taking care of more than 30 patients at the present time. Dirty streets, filthy alleys, impure water and milk and unwholesome foodstuffs, vegetables and fruits, combined with crowded tenement conditions, are said to be among the causes which started the epidemic. Of these evils, the filthy alleys are the most injurious to the health of the public. A committee will be appointed to see that the garbage law is enforced. Steps will be taken to have a more rigid inspection of vegetables and milk sold in the district.

Appointment of Dr. Root.—Dr. Eliza H. Root has been appointed Dean of the Northwestern University Women's Medical School.

The Limitation of Internes.—In a previous issue of the MEDICAL NEWS we referred to the fact that on account of complaints of improper operating by internes at the Cook County Hospital, a rule was put into effect August 1st, that hereafter all major surgical operations must be performed by one of the attending staff. In answer the internes, through a committee, composed of Drs. J. Friedman, J. F. Howard, A. Foerter, O. R. Goldsmith, J. F. Hultgen, have issued the following statements: "(1) *Whereas,* it has been stated that we are but students, learning our trade at the expense of county patients, we emphatically deny this. Every one of us has graduated from a reputable school, has passed the State Board examination and is entitled thereby to practise medicine and surgery in this State, and is selected under Civil-Service rules, by passing successfully an examination in medicine and surgery given every year, competitive

in character, and held under the most rigid and impartial rules that govern any examination whatsoever. Such qualifications are not picked up by the wayside, but gotten only by constant application, by the expenditure of a great deal of time and money. Moreover, every interne in this Hospital has had a college training before starting in the study of medicine. (2) *Whereas,* it has been alleged too much and unnecessary operating has been done by internes. We point out the fact that no operation, at any time, has been performed until after a complete examination by a member of the attending staff, under his direct control and supervision. There is no authentic case in the hospital in which a patient was anesthetized without the presence of an attending physician or surgeon. (3) *Whereas,* considering the qualifications necessary to become an interne, and the fact that every senior interne has served twelve months in preparing for surgical work, it is justly evident that we should be regarded competent to participate adequately in the care of patients. Such privileges are enjoyed by internes of every other hospital in this country and abroad. (4) *Whereas,* . . . It appears as if there were friction between the hospital management and the internes. We assure you that there is nothing but good will between Warden Healy and the house surgeons."

Resignation of Dr. Corwin.—Dr. A. M. Corwin has resigned from the faculty of Rush Medical College as instructor in the department of diseases of the chest, throat and nose.

GENERAL.

Offer of Mr. Slimmer.—Abram Slimmer of Waverly, Iowa, has offered $5,000 to the Chicago Lying-in Hospital, if an additional $10,000 can be raised.

Mosquito Test Fatal Again.—It is reported that two of those who consented to be bitten by inoculated yellow fever mosquitoes in Havana have died.

Diplomas at Only $10 Each.—Three weeks ago Chief-of-Police Benjamin Murphy of Jersey City was informed that the Central University of Medicine, located at 68 Montgomery street, and managed by J. W. Norton-Smith, was doing an illegitimate business, the nature of which was not stated. He made an investigation, but Mr. Norton-Smith denied that he had carried on any business in Jersey City. He said he conducted business by mail only, and would answer no questions except by mail. As Chief Murphy could find no one who had been swindled, he concluded that he had no authority to make an arrest. He informed Prosecutor Erwin and United States Commissioner Linsley Rowe, who approved his course.

Obituary.—Dr. James A. Williams, for more than thirty-five years a practising physician of New York, died on Thursday at Armonk, Westchester County. He had been in failing health for more than a year, but hemorrhage of the brain brought the end suddenly. Dr. Williams was born in Sinking Springs, Ohio, sixty-one years ago. He was graduated from the Rush Medical College, Chicago, Ill., in 1861, and from Bellevue two years later. He entered the army as a surgeon, and was advanced to the rank of major-surgeon, being the youngest in the army to hold that title. Dr. Williams left a widow and daughter. To the latter, Miss Nellie Williams, was presented a gold medal by the United States Volunteer Life Association in April, 1900, for saving the life of her friend, Miss Harris, while bathing at Long Branch. Funeral services were held in Greeneville, Greene County, N. Y.

Dr. James Howard, Jr., of Masontown, Pa., a graduate of Jefferson Medical College, Philadelphia, was dragged to death by a runaway horse at Fairmount, W. Va., August 19th, where he was spending the summer with his brother, E. W. Howard. He was returning from Barnsville, a nearby town, where he had made a professional call, and his horse became frightened. Dr. Howard attempted to jump from the carriage but his right foot caught in the wheel and his head struck the ground. In this position he was dragged 100 feet. When the horse stopped, he was dead. He was twenty-three years old and a son of Dr. James M. Howard. His remains were sent to Masontown.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Own Correspondent.)

London, August 10, 1901.

THE TUBERCULOSIS CONGRESS—PROPOSED INSTITUTE FOR THE STUDY OF TUBERCULOSIS—OPPOSITION TO THE CRUSADE AGAINST CONSUMPTION THE SECRETARY-GENERAL OF THE CONGRESS AND HIS DIFFICULTIES—MR. BURDETT-COUTTS AGAIN ON THE WAR-PATH—THE TRUE INWARDNESS OF HIS CAMPAIGN AGAINST THE ARMY MEDICAL DEPARTMENT.

The Tuberculosis Congress is already well nigh forgotten, with the exception of Koch's sensational pronouncement which has sunk deep into the public mind. Sanitary authorities are making it an excuse for persistence in a policy of masterly inactivity in regard to the supervision of the meat and milk supply, and antivivisectionists are using it as a new argument against scientific research. I mentioned a rumor that Koch had been put up by the German Government to curse all legislation against purveyors of tuberculous foodstuffs; but though he may have been the spokesman of a clique, it is clear that he did not speak for the Government, for an order has been issued by the Public Health Department that there is to be no relaxation in the stringent laws now in force. It is probable that our Government will order a fresh investigation of the whole subject. We have already had two Royal Commissions on Tuberculosis, and the question of the

infectivity of diseased meat and milk was thought to have been definitively settled by the experiments of Sidney Martin. These are in direct contradiction to those of Koch, and as the preparation on which both these investigators based their conclusions were exhibited in the Museum, which was the most interesting part of the Congress, those present had an opportunity of studying the evidence on one side and the other.

It is not unlikely, by the way, that a permanent Institute for the Study of Tuberculosis may be an outcome of the Congress. The scheme has already, I am told, very influential supporters and the time seems to be ripe for its accomplishment. Of course, there will be opposition from some of the high priests of the Temple of Medicine who have persuaded themselves that tuberculosis is a *mare clausum* in whose waters they alone have the right to fish. From such men the organizers of the Congress had to encounter much opposition, all the more difficult to meet that it was mostly of an underhand character. The fact is that the crusade against tuberculosis is viewed with suspicion and dislike by a small, but powerful party in the College of Physicians, most of whom are connected with the Brompton Consumption or similar institutions. Their objection to the crusade is professedly based on its public character, which they affect to think degrading to the medical profession. The real objection is that the initiative did not come from them. Of this, however, they cannot justly complain, for they have had every opportunity of doing something for the repression of a national scourge, and it is their own fault that they did not avail themselves of it. Like the House of Lords in one of Gilbert and Sullivan's operas, they "did nothing in particular, and did it very well." Now that, owing to the impulse given by the *Practitioner,* a popular movement for the stamping out of tuberculosis has been set on foot, and is daily gaining ground, the high and mighty persons who ought to have taken the lead naturally find the time out of joint and are virtuously indignant that they have lost the chance of putting it right.

Great credit is, I think, due to Mr. Malcolm Morris to whose energy and tact the success of the Congress is very largely due. He had many difficulties to overcome, and the Congress had to be steered among sunken rocks and shoals—scientific, financial, and social—where a failure of nerve or a faulty movement meant wreck. The jealousy of some of the men from big provincial towns, where people's manners have not the repose that marks the race of Vere de Vere, showed itself in downright rudeness. It was curious to hear men of science actually denouncing the officials of the Congress for having allowed Koch to deliver his address. Truly if the hierophants of science were to have things all their own way, the *régime* of the Holy Inquisition would be mild compared with theirs. In respect of intolerance theologians cannot hold a candle to scientific men. Malcolm Morris is therefore to be congratulated on having escaped from his persecutors; he intends, I believe, to seek rest in America where he is to deliver the Lane Lectures at San Francisco.

Now that the Congresses have ceased to trouble and organizing secretaries are at rest, we enter on the dull season. All the leading physicians and surgeons are out of town, and Harley Street and Wimpole Street are, in a medical sense, deserted. Deputies do indeed sit at the receipt of custom in place of the oracles who have left their shrines, but business is not brisk. There would be nothing at all to trouble the serenity of the sky, but for an unfortunate accident which has given Mr. Burdett-Coutts an opportunity of going on the war-path again. At the annual meeting of the British Medical Association, held recently at Cheltenham, Sir William MacCormac in speaking of the surgery of war referred to amateur critics who had no idea of perspective and exaggerated everything. The veiled reference was transparent enough, and a newspaper dotted the i's by putting in Mr. Burdett-Coutts's name. That gentleman at once replied in a column and a half of the *Times* in which he repeats his charges against the conduct of the Army Medical Service in South Africa, and indulges in characteristic self-glorification. He tells the world that he struck hard at a deadly sham, and it tumbled to the ground! The effect of his eloquence he says was "miraculous," for "within a week . . . a transformation scene . . . was effected in the military hospitals in South Africa." If we are to take this as a true account of the matter, the word "miraculous" is not at all too strong; for if hospitals in which, according to Mr. Burdett-Coutts's own showing, everything was wrong were put to rights in a few days, a transformation so instantaneous as he describes could have been effected only by a miracle. But miracles, as Matthew Arnold so persistently repeated, do not happen; we are therefore driven to believe that Mr. Burdett-Coutts does, at least occasionally, exaggerate.

I refer to this matter here chiefly in order to correct any wrong impression American readers might get from the utterances of an indefatigable notoriety-hunter. Here, though he tickles the ears of the groundlings, he makes the judicious grieve. The Medical Service has, it is generally admitted, done better than any other branch of the Army in South Africa. Its shortcomings are attributable almost entirely to the War Office which, though warned over and over again that a breakdown must inevitably take place unless a different policy were pursued, persisted in doing everything possible, as of malice aforethought, to cripple its efficiency. It has done and is doing its work on the whole thoroughly well under every disadvantage, and a scheme of reform is now under consideration which will remedy most of the defects in its organization and positions that have hitherto prevented men who had any prospect in civil practice from entering the service Here we quite understand what it is that leads Mr. Burdett-Coutts to play the part of a "wretched, rash, intruding fool" in this matter.

He saw an opportunity of self-advertisement, and thought he would be able to pose as the reformer of the Medical Department. He has been ignored by the Government; hence those tears—and curses!

TRANSACTIONS OF FOREIGN SOCIETIES.

German.

Carcinoma Uteri.

W. A. Freund (Berlin), at the Ninth Congress of the German Society of Gynecology, at Giessen, May 29-31, 1901, read a paper on the subject of the radical operations for carcinoma uteri, with special reference to its permanent results. The possibility of a permanent cure of this affection is presented by two experiences of Freund, namely, a woman who was still well seventeen years after an operation for a recurrence in the body of the organ after an amputation of the cervix for a cancerous node, and another woman who had no sign of recurrence twenty-three years after a total extirpation for cancerous foci in the cervix and fundus. *"Ut cancrum curare, sic eum definire perarduum est."* As to the cause of carcinoma the author is inclined to take sides with the theory of Virchow who claims that irritation is the factor and to assume a waiting attitude as to the more recent theories concerning the elements at work in this disease. Metastatic deposits by way of the blood-channels are very rare in uterine cancer and involvement of the lymphatic glands is relatively a late complication, especially when the parametrium is not affected by contiguity and only in one-third of the cases when it is. This position he holds contrary to the teachings of Wertheim. In cancer of the cervix extension usually occurs sidewise through the parametrium and finally approaches the tissues about the rectum in the hollow of the sacrum. Inoculation recurrence is naturally after operation only possible under the theory of the essential infectiousness of cancer. These facts all plead prompt operative interference. The new century must necessarily bring toward final settlement the vexed question as to the choice of methods of approach. In general terms the more fully in view a field is, the better. Therefore the abdominal route is by far the best. Contrary to the general attitude of the German surgeons, the British surgeons are coming to the stand that the operation for uterine cancer is of limited application. Unfortunately the statistics on this subject give us little aid at present.

Winter (Königsberg) read a paper on the question of the radical operations and enumerated as the chiefly available (1) supravaginal amputation of the uterine cervix; (2) vaginal total extirpation; (3) abdominal total extirpation; (4) radical abdominal operation. A very particular advance over the earlier methods of treatment is offered by the radical abdominal operation which permits not only a thorough clearing away of the parametrium, but also a removal of the lymphatic glands. These glands have been found to be diseased in from 35 to 50 per cent. of the cases. Up to the present we have 134 records of this radical operation with a mortality of 24.6 per cent., of which 18 were by infection and 12 by late collapse.

Schaute, Wertheim and Winter have each seen a fatality in this operation result from necrosis of the ureters. Therefore it is advisable not to loosen these too widely and too roughly from their beds in the retroperitoneal connective tissue. It is interesting to note that Winter usually ablates the uterus through the vagina. If, indeed, it is too large to permit of this step, he amputates the uterus just above the cervix with the Paquelin cautery and then ablates the stump of the cervix through the vagina, together with any possibly affected vaginal wall. This process Wertheim shortens by clamping the vagina just distal to the cervix and then when all is away uniting the peritoneal wound over the free end of the vagina. Winter hopes that progress will be made not through extensive operation, but through early diagnosis and promptly undertaken interference. He closed with a plea for fair-minded and truthful statistics.

Kustner (Breslau) discussed the abdominal approach to the uterus and by means of charts showed the distribution of the lymphatic channels. His position is that although the theoretical considerations are on the side of the abdominal operation, the vaginal route has by far the best statistics and appears to be a much less fatal method. The peritoneum must as far as possible be kept out of all contact with the carcinoma. The procedure of Veit seems to offer alike the best records and the best method of avoiding any poisoning of the peritoneum and consists chiefly of beginning the operation above and finishing it below. When the uterus is deeply sunken into the cavity of the pelvis, it is best not to close the peritoneum after having taken the uterus out by the vaginal route. Küstner takes two strips of gauze and sews them carefully to the uterus just before it is removed so that while they traverse the wound they cleanse it. He regards as more important full protection from the carcinomatous pus than the ablation of remote lymph-nodes. He also holds that probably in the future we will remove affected segments of the bladder and ureters.

SOCIETY PROCEEDINGS.

BRITISH MEDICAL ASSOCIATION.

(Continued from page 275.)

Section of Psychological Medicine.

Asylum Administration.—Dr. J. B. Spence read this paper in which he brought out the differences in the treatment of the insane as they existed in the earlier years of the century and the conditions found at the present time. To Tuke, Conolly, Brown, Mauds-

ley, Clouston and others have been due this progress in the amelioration of the condition of this type of diseased humanity. To some of these have been given gifts the exercise of which has enriched the pages of literature with the result of their researches; to others the more humble but perhaps hardly less useful talents for organization, for planning suitable accommodation for the various classes of the mentally ailing, and the capacity for paying attention to the numerous small details which in great measure go to make up the sum of human life, and which tend materially to promote the comfort and happiness of the individual and benefit the insane mind by ministering to the bodily wants of those who are so afflicted.

Lay Management.—He further said: "I heard it said not long ago that there was a feeling abroad in favor of lay management of our large asylums. Well, to those of us who have lived long enough this is nothing new. Ideas occur in cycles, and what to the experienced is but the repetition of an oft-exploded theory comes to those who are new to the subject, and who have not given it much consideration, as something which, to put it at its lowest, merits at least a trial. It does appear to me that in few other positions is the combination of the medical man with the good organizer so necessary as at the head of an establishment in which the treatment of the inmates is not purely medical nor purely reformatory nor merely curative, but where many methods must be employed if ultimate success in dealing with the variety of types which come under our care is to be looked for. The day is past for the expression of the cheap sneer involved in the story of the hypothetical superintendent who, when asked to see a patient, excused himself on the ground that he had just been urgently summoned to the farm where his favorite sow was littering and must be visited at once. If one desired to do so it would be possible to tell an equally good, and in all likelihood an equally untrue, story which might place the scientific side of our work in as false a light, but it is not my wish to decry, even in a joking fashion, good work of any kind, my only desire being to emphasize the point that the argument which has been brought forward in favor of lay government, and which is expressed by the statement that a doctor should stick to his work and leave the management to those who are supposed, often erroneously, to know more about it, is an incorrect one, as the main objects of an asylum—namely, the cure, care, and comfort of the patients, would be thereby frustrated, for all these can only be successfully carried out under the supervision of a man who, to the groundwork of medical training has added the experience which he, being presumably a cultured individual, is at least as capable of acquiring as the man who has merely served in an office or behind a shop counter."

Large Asylums Not Desirable.—"It is in this connection that I so regret the establishment of the huge asylums to which unhappily use is accustoming us. In the medium-sized asylums there is just that amount of work which any man who is worthy of his position should be able to supervise with due attention to the various departments into which the establishment must necessarily be divided, and where the one governing mind can so utilize the means of treatment placed at his disposal that whether the individual patient —known to the chief by name, by disposition, in his family relationships, in his special characteristics, and in his necessities—requires medical or moral treatment, the care of the sick room, or the exercise of the garden or farm, the quiet of the cosy ward, or the stimulating effect of the workshop, each can be brought into play without the risk of producing that friction which practical experience has shown to be not infrequently present when more than one controlling influence is in operation. As a question of expense, I have yet to learn that the medium-sized asylum is more costly in its management than the large establishments which, while they excite the wonder of the inexperienced, produce only feelings of regret in the minds of those who have to govern them. Nor have I had it proved to me that better results have been produced either in the treatment of the insane individual himself with regard to promotion of his recovery, the increase of his comfort when in fair bodily health, or his treatment when attacked by illness, physical or mental."

Separate Treatment of Dements.—Dr. Pearce was outspoken in praise of the movement now to be put in practice in this country of making special provision for the demented insane. These do not require the same amount of care as the acute insane and the agricultural colony system is an ideal one, although it is true that even the individual lowest in the scale of mental degradation can appreciate the bright and comfortable surroundings of the average county asylum. But when all is urged that can be brought forward to support this side of the question, the opinion is justified that while no expense should be spared to provide the necessary appliances and the most favorable environment for the curable, yet in a distinctly appreciable proportion of the incurably insane and the mentally deficient, a kindly, judicious, and truly philanthropic system of treatment might be adopted without loss of benefit to the class in question, and at a much reduced cost to the long-suffering ratepayer.

The Acute Insane.—As to the form in which accommodation should be provided for those suffering from mental disorders of a curable nature, it is a distinct advance that the trend

of educated opinion in this country is in favor of segregation, and all alienists are looking forward with interest to the result of the experiment which has been taken in hand by the East Sussex County Council, and by the authorities whose duty it is to provide accommodations for the insane poor of Edinburgh and Aberdeen.

Laboratory Methods.—The opening of an experimental psychological department in connection with the well-known pathological laboratory at Claybury is one more evidence of the interest taken in the work of the alienist by that progressive body, the London County Council, and the establishment of central laboratories in connection with the county asylums should open out a wide field for investigators who would be able to devote their entire time and energy to the study of the origin of the various mental disorders met with in practice; so that, while a glance backward reveals how much has already been done in the direction of clearing away some af the doubts which have been from time to time suggested as to the curability of insanity, one may look forward with hope to the coming century as a period during which, to put one's anticipations at the very lowest, much may be effected in the direction of prevention, even if the cure of sufferers from chronic mental disorders must remain—as in the case of many who are afflicted with bodily diseases—subjects for that humane care and attention which is the daily, trying, but noble work of many physicians.

Toxins in the Pathogeny of Insanity.—Dr. Ford Robertson opened a discussion on this subject in which he spoke more particularly of the relation of general paresis to metabolic toxemias. In general paresis gastro-intestinal disturbances are very common. Chronic trophic catarrhal processes of the intestinal canal are very widely present and in consethere is deficient metabolism and toxin formation, which toxins are absorbed by the lymphatics and thus enter into the general circulation. They contribute largely, he thinks, to the damage done to the cerebral tissues, both nervous and vascular. Special importance was attributed to syphilis, alcohol, auto-intoxication and auto-infection from the gastro-intestinal tract in producing just such lesions. The disease in which such action is manifest are the various manifestations of arteriosclerosis, senile insanity, paresis, locomotor ataxia, alcoholic insanity, dementia, acute and chronic mania, melancholia and chronic Bright's disease. The larger number of cases of insanity are not primary diseases of the brain, but are due to the action of toxins in the cortical neurons by disordering their metabolism and often permanently damaging and even destroying large numbers of them.

Treatment of Neurasthenia.—Dr. A. Schofield included under this term the general neurasthenic diathesis, hysteria, etc. In their treatment the most important factor was the personality of the physician. In regard to hysterical diseases it was important for the physician to bear in mind that diseases of the imagination are not imaginary diseases. Hysteria and neurasthenia, he thought, both arose from disorder of the subconscious mind. Sexual excesses were important and needed careful treatment. Open air and careful dietary were necessary. Neurasthenia was more benefited by rest than by exercise; overfeeding was important. Hypnotism, he thought, was of doubtful service. After convalescence the patient should not return to his old surroundings and habits, if possible.

Anthropometrical Examinations of Asylum Patients.—Dr. E. Goodall read a communication embodying many of the ideas of the French and Italian anthropological alienist devotees, in which he advocated the taking of such measurements as a routine for the asylum work.

Puerperal Insanity.—Dr. Robert Jones of Claybury opened a discussion on the subject, in which he said that in one in 1,700 confinements insanity developed in the mother. This condition was four times more prevalent following illegitimate births. Of the cases at Claybury 269, or 7.4 per cent., had had puerperal insanity. The commonest type was marked by delirium with hallucinations and mingled with religious and erotic excitement. The prominent symptoms were insomnia, headache, restlessness, apprehensiveness, auditory and visual hallucinations and dangerous impulses toward suicide and infanticide. Treatment was by generous feeding, electric baths, and hypnotics. Relapses occurring during convalescence are of bad import.

Physical Basis of Melancholia.—Dr. John Turner read this paper. Certain of the nerve-cells of the cotex, he said, present an alteration in appearance in many cases of melancholia and dementia (alcoholia). The change is similar to that which follows when the axons of the fore horn cells or those of the pontiæ nuclei have been severed. But examination of the axons (in the cord) shows that in melancholia the change is not produced primarily by interference with the axons. The change has also been noted in melancholia by Wiglesworth and others. The distribution of the lesions were as follows: The pyramidal and giant cells of the so-called motor cortex show it most clearly; in this region most of the cells being affected. It is commonly met with in the frontal and occipital regions, especially in the large cells of the latter. Of all the nuclei examined in cross sections of the medulla oblongata-hypoglossal-vagus-lateral, ambiguous, gracile, and cunette, only the first escapes, all the others show the change affecting generally the major proportion of the cells. In the cord the cells of Clarke's column are

early affected and ultimately in advanced cases the forehorn cells. In the posterior-spinal ganglia, while only a few cells show the change, many are altered in another way—densely stained and very shrunken. In the tracts of the cord only in very advanced cases is there any sign of degeneration of the myelin sheaths, and then it is the crossed pyramidal tract (axons of motor cells of cortex) which is affected. The pathological observations indicate that the cause which brings about this change is not a general one, operating on all parts of the nervous system, such, *e. g.*, as a perverted state of the blood, otherwise we should expect to find all the cells of a similar type participating in the change. This, as has been shown, they do not. Another point brought out is that the change early affects cells, and notably those of Clarke's column. The experiments of Warrington show that this change can be produced in the cells of Clarke's column by division of the posterior roots, and he assumes that in this case it is due to depriving these cells of the ingoing stimuli normally passing to them. Thus it has been established experimentally that this change can be set up in at least two ways, namely: (1) By agents having a destructive action on the axons of the cells in question (traumatism, and probably also alcohol), and (2) by agents which do not primarily affect the axons of the affected cells. These observations indicate that the melancholic cases fall into the latter class, and, further, that the state of the mind is an essential factor in inducing the change. The deprivation of the nerve-cells of their normal ingoing stimuli is the explanation offered in accordance with the writer's hypothesis that melancholic states depend on dissolutions of the nervous system affecting the sensory or ingoing section of the nervous reflex mechanism. Clinical observations from Griesinger and others are also given in support of this contention, notably the very general occurrence of anesthesia in melancholia.

SECTION OF DISEASES OF CHILDREN.

Treatment of Intussusception.—Dr. B. Pitts of London gave an analysis of all the cases occurring in surgical wards of St. Thomas' Hospital from 1875 to 1900. He pointed out that distention of the bowel might be tried, if the case was very recent, under an anesthetic and holding oneself in readiness to do an abdominal section, if necessary, at once. A severe case should at once be explored, without any previous inflation, as this only added to the shock. The intussusception should be brought outside the wound, as then the condition could be examined. If reduction were impossible resection of the bowel should be done. If gangrene were present the case was almost hopeless, as prolonged operations were not well borne by children. The sooner the child was placed in the hospital after the symptoms appeared the better. At the first onset it seemed reasonable to inflate the large bowel, but it was never certain that inflation completely reduced the swelling, and the uncertainty as to the exact condition of the bowel made it better for the surgeon to see and to handle it. The swelling of the mesenteric glands which occurred in children in intussusception, hindered reduction. Inflation might be used as a preliminary to operation. The risk of shock must be minimized by all possible means in a young child. It was better not to let the small bowel escape out of the incision, so if there were very much distention he would make a small opening into it and let out the contents—*i. e.,* gas—and then sew it up. A great danger of reduction was the chance of splitting the coat of the bowel. If reduction were very difficult he would open the sheath and reduce by a finger inside the bowel. If this were impossible he would resect the bowel *in situ*. He then referred to a diagram of a case of ileo-colic intussusception where the portion inside the colon was removed, and to another where there was invagination of the appendix. In a third case the small bowel was implanted into the large one above the old ileo-cecel valve. In a gangrenous case twenty-four inches of bowel were removed. Saline injections were of great service. The suturing of the abdominal wound should be very thorough and the stitches should be left in for a long time so as to have no prolapse of the intestines. According to the list of cases chronic intussusception was quite rare in children. In fatal cases the temperature frequently ran up at once after operation to a great height from no very certain cause. In cases brought to hospital it was better to operate at once and to try inflation also so as to get the bowel back to near where the incision should be made. In gangrenous cases the ends of the bowel should be brought outside the body and continuity should be established later. If very extensive, resection and restored continuity with Paul's buttons should be done at once.

Acute Specific Fevers.—Dr. Foord Caiger opened this discussion. He advanced a provisional classification of specific fevers based on a recognized similarity in their clinical aspect during the early period of illness. In this way a group was obtained characterized at an early stage by catarrh of the naso-respiratory tract, and by pyrexia, the group including measles, rubella, the ordinary febrile cold, and whooping-cough. The frequency of occurrence and diagnostic significance of Koplik's spots was alluded to and the spots themselves minutely described. Dr. Caiger considered them of absolutely certain import when found, but he had not found them present quite as often as some other observers. The diagnosis of certain affections attended with laryngeal stridor was next discussed, and a further group was suggested of those cases which were attended with febrile sore throat, namely, tonsillitis, diphtheria, and scarlet fever. Points of difference between diphtherial sore

throat and follicular tonsillitis were alluded to. Several axioms were laid down with reference to the diagnosis of diphtheria bacteriologically and clinically, and the value of Neissner's stain in making a positive bacteriological diagnosis of diphtheria was dwelt on. A diagnosis should never be based on a bacteriological examination alone. The differentiation of those diseases which resembled each other by the possession of a diffused erythematous eruption, namely, scarlet fever, measles, and rubella was also considered. Dr. Goodall referred to the time at which the rash in measles appeared, the prodromal rashes of measles and varicella, the remission of symptoms occasionally observed, the diagnostic value of Koplik's spots, the difficulties in diagnosing scarlet fever, and the question of the incubation period in that fever. Dr. Ashby alluded to the occurrence of Koplik's spots and the incubation period in measles, and raised a question as to the spasmodic cough occurring after influenza, the importance of recognizing large glands at the angle of the jaw as a means of diagnosis in diphtheria and scarlet fever, and the characteristic rashes of empyema and pneumonia. Dr. Poynton described some difficult cases that had come under his notice in a public school, and referred to the rash that might be due to iodoform poisoning. Dr. W. J. Tyson referred to the difficulties of diagnosis in obscure cases of so-called "gastric" and typhoid fevers. Dr. Watson Williams showed drawings of Koplik's spots, and gave his experiences in two epidemics of typhoid and measles respectively. Dr. Lovell Drage urged the importance of looking on every sore throat as a possible source of diphtheria, and deprecated the looking at every sore throat as a separate entity. Dr. Mansel Sympson referred to the enlargement of the posterior cervical glands in German measles, and to questions of the heat of the skin and convulsions in early stages of infectious disease.

Miscellaneous Papers.

Arresting Acute Endocarditis.—Dr. R. Caton of Liverpool thought that progress had been made in understanding the endocarditis of acute rheumatism and that it would not be long before the microbial origin of the disease would be absolutely recognized; not so much progress had, however, been made in the treatment of the complaint. He described the results of his treatment in 92 cases of endocarditis arising in the course of acute rheumatism while the patient was actually in the hospital. He insisted on three points. First, absolute rest in bed for at least six weeks on low diet; second, that salicylates did not do so much good to the heart as to the joints, and that such drugs as digitalis, strophanthus, etc., were on the whole injurious. Small blisters applied in succession over the præcordial area were very valuable and he discussed the action, or possible action, of these in exciting resistance to bacterial growth in the tissues of the cardiac valve. Thirdly, he gave sodium iodide with a view to promote absorption of the effused fibrinous material on the valves. He considered that in many of his cases he had quite prevented the extension of the disease and many were now in good health after considerable periods.

Professor Osler thought that they owed a distinct debt to Dr. Caton for his attempts to combat with what was undoubtedly the most serious part of acute rheumatism. He had followed out the treatment and was sure that it was the correct one, but he regretted to say that he was afraid it could only be of advantage in a few cases. It was very desirable to obtain a subsequent history of the patients at a later stage, as frequently the ultimate damage caused to the valves only became apparent after a considerable interval.

Gastro Jejunostomy in Ulcer of Stomach and Duodenum and Pyloric Stenosis.—Dr. G. Barling of Birmingham remarked on the difference in the estimates of mortality from gastric ulcer, and considered 10 per cent. to be approximately accurate. This mortality was due to perforation, hemorrhage, inanition, intercurrent disease, and cancer. A cancerous change he believed to be rare. The diagnosis was often very difficult, and neither the occurrence nor absence of hemorrhage permitted of certainty in forming a positive or negative opinion. The conditions calling for operation appeared to be in the first place hemorrhage; in acute "fulminating" hemorrhage surgical intervention was of little use; in recurrent hemorrhage either gastro-jejunostomy or direct treatment of the ulcer were the methods of choice. The second class in which operation was called for was formed by the cases of long-continued pain, vomiting, loss of weight, and repeated disability for work. Thirdly, there were the cases where gastric dilatation and stasis pointed to pyloric stenosis; and, fourthly, there were those where adhesions were the cause of stenosis or pain. The method of Loreta—pylorodosis—he did not favor, owing to the danger of rupturing the coats if efficient dilatation was carried out. Pyloroplasty was the method of choice in pyloric stenosis, except in cases where the pyloric thickening is very dense and there were many adhesions. It was inapplicable in cases of duodenal ulcer and where an operation was undertaken for the relief of pain and hemorrhage. The simple separation of adhesions was an incomplete procedure. In regard to gastro-jejunostomy he had only performed the anterior operation, and with fair success. He did not favor any method of special approximation. Delay was the chief cause of mortality after operations; the mean mortality of gastro-jejunostomy was about twenty per cent.

Thyroid and Oophorectomy for Cancer of Breast.—Dr. G. T. Beatson of Edinburgh said he brought this matter forward to open discussion on the experience gained during the five years since the procedure was described in *The*

Lancet, July 11, 1896. He gave an account of a case which he thought exemplified the beneficial effects of the treatment in a remarkable manner, for within a period of six months a large cancerous mamma had entirely atrophied and the extensive glandular enlargement present before the operation had disappeared. He made mention of what Mr. Watson Cheyne had called this "striking" control of the course of carcinoma of the female breast of oophorectomy and thyroid feeding, as furnished by other surgeons. He raised the question of the possible explanation of such results, especially in the light of those cases of apparently spontaneous disappearance or quiescence of mammary carcinoma. Cases where improvement resulted from oophorectomy he thought might bear on the etiology of the disease, since he regarded the apparent controlling influence of the ovaries as inimical to the parasitic theory of the disease. There arose further the big question, Did these results justify the adoption of such treatment as a primary method in the early stages of the disease? In concluding, he affirmed his confidence in the utility of the combined oophorectomy and thyroid feeding in cases where direct operation on the disease was impossible.

Experimental Glycosuria.—Dr. F. W. Pavy of London said that glycosuria might be taken as meaning the presence of sugar in the urine in quantity sufficient to be recognizable by the ordinarily employed rough methods of testing. Strictly speaking, however, normal urine contained a certain amount of sugar which escaped being revealed by rough testing but which was susceptible of recognition by more delicate methods of procedure. This was not taken into account in connection with the consideration of glycosuria. Under normal circumstances, although carbohydrate matter might enter largely into the food ingested, no glycosuria was observed. It therefore followed that the system had the power of dealing with it in a manner to obviate its escape in an unutilized state, as sugar, with the urine, and he thought it might be said that the physiologists now for the most part concurred with the view that it was placed in a position for utilization and its escape as sugar thereby was prevented by the assimilative action of protoplasmic matter. Living protoplasm was endowed with the power as a property throughout nature of taking appropriate matter and incorporating it into itself. In this way absorbed alimentary carbohydrate became drawn into the proteid molecules of which protoplasm consisted —for the essential constituent of protoplasm was proteid—and subsequently subjected to the influence of conditions resulting in one way or other in utilization. Assimilation thus stood as a preparatory step to utilization, and when the absorbed carbohydrate of food was fully assimilated and afterwards properly turned to account no glycosuria occurred. Experimentally induced glycosuria carried them over a vast extent of ground. The conditions giving rise to it were multitudinous and diverse. Here Dr. Pavy gave a list of conditions leading artificially to the production of glycosuria. With such a chaotic list before them it was difficult to see upon what ground they stood with respect to the manner in which the several conditions acted in producing glycosuria. The best way of meeting the difficulty would be, it appeared to him, to look to the sources from which in connection with the operations of life the eliminated sugar could be derived. Thus viewed the origin of the sugar of glycosuria could be shaped for consideration under four heads: (1) It might be derived from unassimilated carbohydrate; (2) it might be derived from stored glycogen abnormally passing into sugar which thereafter found its way into the urine; (3) a third source for the sugar of glycosuria was proteid matter (by an abnormal breaking-down process sugar became cleaved off and subsequently eliminated in the urine); and (4) the question of a fourth source from fat would be discussed. They knew that as a normal occurrence in the vegetable kingdom fat was extensively converted into carbohydrate. It was a matter for consideration if under abnormal conditions fat in the animal kingdom could constitute a source of sugar in connection with glycosuria.

Fibroids; When and Why Operate.—Dr. William Duncan opened this discussion. He said: The direct mortality from fibroids was a matter of controversy, but could not be non-existent, as one author had collected eighteen cases in which death was directly due to such tumors. The danger to health, however, was far more important as regarded the general question of operation. Many fibroids should be left alone; others caused hemorrhage—not to be disregarded —pressure on the bladder, rectum, or sacral nerves, or exhibited a rapid growth, or complicated pregnancy, and in such the question of operation immediately arose. The uterus should in the first instance always be dilated and explored; polypi might be removed, or a small submucous tumor without a broad attachment twisted out. He was not in favor, if the submucous tumor were large, of the plan of slitting the capsule, giving ergot, and trusting to the uterus to expel the tumor; nor of *morcellement*, which he considered as dangerous as hysterectomy. Myomectomy was no doubt a good way of dealing with subperitoneal growths, if single and not widely attached. He had found that the Apostoli method neither reduced the size of the tumor nor arrested the hemorrhage. Generally he preferred hysterectomy by the abdomen, and, though panhysterectomy was occasionally necessary, he had up to the present time performed intraperitoneal hysterectomy in 127 cases with 4 deaths, none of which occurred in the last 81 cases. Rapid growth of fibroids implied cystic or mucoid degeneration, and always demanded operation. In case of pregnancy, if the tumor were in the upper uterine segment, or subperitoneal and not impacted in the pelvis, it should be seldom interfered

with; in other cases the question to decide was whether we should empty the uterus, perform hysterectomy immediately, or wait till term and remove the uterus after Cæsarian section. The administration of strychnine for a week before and after operation was a valuable method of avoiding shock; hot water with bicarbonate of soda was of benefit in tympanites; nutrient enemata should be given every four hours. The ovarian and uterine arteries should be tied on both sides before amputation; the cervix should be completely covered by the peritoneal flaps, but the cervix should not be stitched, or the knots should be outside the peritoneum. Mr. Alban Doran pointed out that "retroperitoneal" was a more correct term for the hysterectomy described by Dr. Duncan than "intraperitoneal." Even interstitial fibroids if near the fundus were of little detriment to pregnancy. Not only should any sutures passed through the cervix be kept outside the peritoneum, but all stumps (of the ovarian arteries and tubes if amputated) and ligatures upon them should also be excluded. If there was any doubt as to the position of the uterine arteries it was better not to attempt to tie them till they spouted.

Maladies of European Children in Hot Climates.—Dr. A. Crombie said that, speaking generally, it might be said that the sick-rate of European children was lower in India than in the United Kingdom, the reverse to the death-rate. It was therefore obvious that the illnesses of European children were more frequently fatal in India. Were, however, malaria excluded from the diseases in India, the British child in India would have less chances of illness by 10 per cent. than the child at home. From army statistics it was shown that diseases of the alimentary canal, although generally believed to be more prevalent in India than at home, were not really so; it was the gravity of the affections in India that caused alarm. The admission rate for all tuberculous diseases appeared to be higher among European children in India; but the death-rate and case-mortality were both lower. Dr. Edward Henderson said that in Shanghai, with a subtropical climate, children appeared to suffer more during the hot months than adults. Heat not only caused bodily languor and anemia, but in addition made food was less wholesome. Bottle-fed infants were much more apt to suffer than breast-fed infants.

Disposal of the Wounded in Naval Actions.—Fleet Surgeon G. Kirker, R.N., opened this subject with a practical paper divided under three heads: (1) The surgeon's station, or the place where the wounded are treated; (2) the time of treatment: (3) the conveyance of the wounded. He said that it had always been the custom to select some well-protected and easily accessible part of the ship for the reception and treatment of the wounded and to convert it before action into a special surgical station. In the old wooden battleship the "cockpit" or after-part of the orlop deck—a place below the water-line and approached by a wide hatchway—was universally selected as the surgeon's station, and many of the scenes which had occurred there had found their way into history and art. When the iron battleship displaced the wooden one the "orlop deck and cockpit" disappeared and naval surgeons lost their prescriptive station in action. Then the captain and medical officer selected the place they thought most suitable. In this way the location of the surgeon's station was settled and owing to variations of ship-construction it would be so settled until a proper modern operation-room or modern "cockpit" was fitted up. This operation-room should be included in the internal arrangements of every modern battleship and cruiser. It need not be large and it should meet the requirements of aseptic surgery. It need not be particularly easy of access for with a properly devised ambulance sleigh the wounded man could be easily and safely taken down and along all hatchways and passages. During peace important surgical operations could be done in the operating-room and valuable surgical instruments and necessaries could be kept there. In time of war the surgical accessories would be protected during action, and after action operations would be done with more chance of success than occurred in bath-rooms or greasy mess-places. The preservation of the lives of the surgeons and the safety of appliances during action would prevent such disasters as occurred on board the Japanese ship *Hiyei* at the battle of Yalu. In this ship a shell entered the wardroom, in which the cockpit was located, killing surgeons, nurses, and wounded, and destroying all surgical appliances. With regard to the time of treatment, it was the rule in time of war to remove the wounded at once to the dressing station. In modern warships it would not be practicable to remove the wounded during action; they would be left to wait for a lull in the fighting. The Japanese found that the surgeons could do no really good work till after the action.

Skin Diseases and Light Therapy.—Dr. Malcolm Morris of London opened the discussion on the Finsen light and X-ray methods. He directed attention chiefly to the application of this treatment to lupus. In northern latitudes the sun could not be relied upon altogether, and therefore the electric light must be had recourse to, which in point of fact was therapeutically more active. In respect of current he had found one of about 70 ampères and 60 volts sufficiently strong to produce the effect required in most cases, and it had been thought better to shorten the time of exposure rather than to lessen the intensity of the light. In order to get a powerful light it was most important (1) that the lenses, especially the bottom one, should be clean and bright, and (2) that the water should be clear and free from floating particles. The bottom lens should be thoroughly cleansed and polished every day—a detail which was greatly facilitated by having it made detachable. Up to July, 1901, the total number of cases treated at the establishment under his

direction was 60. In 36 of these the disease was lupus vulgaris, in six lupus erythematosus, in 13 rodent ulcer, in one doubtful rodent ulcer, in two alopecia areata, in one cheloid, and in one epithelioma. Of the cases of lupus vulgaris eight might be claimed as instances of cure, in three the treatment was abandoned on account of failure of health, while in six the result was unsuccessful or unsatisfactory. The remainder were still under treatment. Of the cases of rodent ulcer seven were cured, in two the unsatisfactory state of the patients' health made it impossible to go on with the treatment, and two were still under treatment. Of the cases of lupus erythematosus in two the result was satisfactory, in three the treatment had to be discontinued, and one was still under treatment. Of the cases of keloid and epithelioma nothing definite could yet be said. In the successful lupus cases the number of sittings varied from 8 to 370. They were mostly favorable cases, in which the disease was superficial and of small extent. Brief notes of the cases were then given.

Rationale.—The application of the light was followed by an inflammatory reaction consisting in hyperemia and redness, followed by the formation of a bleb which broke and dried in about a week into a thick yellow crust. Healing was complete in ten days or a fortnight. In places where the tissues were loose—for instance, near the eye—there was often great swelling of the neighboring parts. The intensity of the reaction varied in proportion to the intensity of the light and also according to the structural peculiarities of the patient's skin, and especially according to the local conditions produced by the disease. In persons with thin skins the reaction was greater, while it was less marked in coarse thick skins. The reaction came on from five or six to twenty-four hours after the application of the light. It was usually slight at the beginning of the treatment and sometimes became greater as it was continued. Even after prolonged treatment it still showed a tendency to increase rather than to diminish. The Danish physicians said that the treatment was painless, but this was not strictly accurate. There was, indeed, seldom anything that could be called pain at the time the light was applied, though sometimes a feeling of heat was experienced. But the after-smarting was often considerable, and the inflammatory phenomena constituting the reaction were also more or less painful. There was seldom any constitutional disturbance. In the case of ulcerated surfaces there was, of course, no blistering or crusting; a much larger number of consecutive applications could therefore be made without inconvenience to an ulcer than to an area of intact skin. Reaction was manifested by redness and soreness which were sometimes accompanied by some swelling of the surrounding parts and great tenderness on pressure. These effects were seen about the fourth or the fifth day, and if the applications were kept up the skin around the ulcer became inflamed. According to Mr. Morris's experience the remedial effect of the light rays was directly proportionate to the intensity of the reaction; the production of a considerable reaction should, therefore, always be aimed at. If the disease extended into the deeper layers of the skin, and if there was much scarring, this formed an obstacle to the penetration of the light rays. Another circumstance which made the passage of the rays increasingly difficult when the treatment was prolonged was the pigmentation caused by the frequently repeated applications of light. The amount of pigment naturally present in the skin must also be taken into account. Brunettes were not such good subjects as blondes, and the darker they were the less amenable were they to the light treatment. Hence there were great difficulties in applying it to patients of black or mixed race. When the disease extended deeply and there was great thickening and infiltration of the tissues—*e. g.*, from previous treatment by other methods—it was difficult for the light to penetrate and a large number of exposures were required to make an impression on the mass of diseased tissue. The large extent of the area involved was sometimes a most serious difficulty, as only a small spot could be treated at a time, and thus it was scarcely possible to deal with all the nodules as they developed on the edge of the patch. The only hope of keeping pace with the disease in such cases was to retain the patient under treatment two or three hours daily. This was seldom possible as the patient could not spare the time or tolerate the prolonged immobility required. Moreover, the reactions tended to become so severe that they could not be borne. Cases in which mucous cavities were involved were unfavorable for the light treatment, but in such cases X-rays were useful owing to their power of penetration. If the disease were extensive the treatment must at the best be tedious. It should be applied daily on six days a week if there were nothing—as, for instance, excessive reaction—to make interruption necessary. In cases where there might be a special urgency the treatment might be carried out twice a day without any ill effect. The success of the light treatment depended more on the attendant who had the actual management of the details than on the medical men who had the supervision of the case. Her duties required not only intelligence or skill, but devotion.

NEW YORK COUNTY MEDICAL SOCIETY.

Stated Meeting, Held May 27, 1901.

The President, George D. Fowler, M.D., in the Chair.

Blood Alkalescence.—Dr. Heinrich Stern of New York said that blood alkalescence depends to a large extent on the amount of carbon dioxide in the blood. There is less carbon dioxide exhaled at night, because the breathing is more infrequent and, as a consequence of a certain accumulation of the acid gas in the

blood, the blood itself is less alkaline and the urine more acid. The degree of acidity of the urine in series of individuals does not follow a general law, but is eminently special for each person. It is to a certain extent a function of respiration, because the removal of carbon dioxide depends on respiration. The depth and number of our respirations differ for each individual. The amount of air breathed by persons of the same weight and build may be quite different. The presence of alkaline carbonates in the blood may contribute to lessen the acidity of the urine. The urine can even be rendered alkali by their administration. While the alkalescence of the blood bears a certain relation to urinary acidity, the degree of blood alkalescence is not a very variable quantity. It is not difficult to bring about changes in the degree of acidity of the urine. Only very slight variations, however, can be produced in the degree of blood alkalescence. The alkalinity of the blood seems to be one of the stable factors of the organism whose alteration would lead to serious disturbance of all important functions.

Personal Experiences.—Dr. Stern tried a series of experiments and observations on his blood alkalescence and its relation to urinary acidity. He took the same amount of water, about twelve hundred cubic centimeters, every day. Variations in the diet by which food values of from 800 to 1,700 calories of foodstuff were consumed did not produce corresponding variations, nor, in fact, any notable variation at all, in the alkalescence of the blood. It seemed to make no apparent difference whether the food employed was largely proteid or largely carbohydrate in composition. As the result of his experiment Dr. Stern was able to formulate the following influences: (1) As a rule, the higher the acidity of the urine, the lower the alkalescence of the blood, but there is no direct ratio between these two fluids; (2) the influence of ingesta on blood alkalescence is practically *nil*, neither the quantity nor the quality of food materials consumed modifies the alkalinity of the blood in any known direct way; (3) the urinary acidity is modified by the direct transfer of salts which are absorbed in the intestinal tract and are at once eliminated in the urine. Blood alkalescence is modified by the respiratory function.

Ingesta and Acidity of Urine.—Dr. L. Fougères Bishop said in discussing the paper that Dr. Stern had shown that the acidity of the urine is independent of the quantity or quality of ingesta. Blood alkalescence and urinary acidity normally follow a physiological cycle, which produces a series of changes not unlike the temperature curve of the day in normal individuals. While the reaction of the blood is due to a very complex set of influences, blood alkalescence is extremely uniform, and this uniformity seems necessary in order to preserve health. The hydrochloric acid that is so indispensable to digestion is somehow derived from the blood. Its presence in the stomach and the influences that lead to its formation may be the basis for the changes that cause diminished acidity of the urine after meals. At this time the kidneys have, as it were, less acid material to excrete because a certain amount of the acid present in the body has been secreted into the intestinal tract from the stomach-walls. Speculatively we have been acustomed to think of blood alkalinity as a quality that could be varied almost at will. Experiment shows its permanence and adds a new item to our knowledge of stable human metabolism.

Pregnancy After Myomectomy.—Dr. James N. West read a paper on this subject, advocating conservatism in gynecology. He pointed out the fact that in a great many cases myomata can be removed, leaving the uterus to perform its maternal function afterward. With regard to the treatment of myomata, there has been a great variety of opinions. A cycle of teachings from overconservatism, embracing treatment by drugs and by electricity, to needless mutilation involving the radical removal of the uterus whenever a myoma was present, has been passed through. Between these extremes, both worthy of condemnation, there is a middle course to which conservative gynecologists are rapidly being converted.

American Experiences.—In 1884 Emmet reported his own experience with myomectomy. He had performed five operations, but all of his patients succumbed. He collected over three hundred cases from the literature and showed that, even in the best hands, the mortality of radical treatment of myomata was at least 47 per cent. He warned the general practitioner that he must not expect to be even as successful as this, and must not hope to save even one out of every two patients. As a marked contrast to this opinion, Dr. West quoted the declaration of Kelly of Johns Hopkins, made last year, that myomectomy may be performed without any danger, and that the uterus may be left to perform its function as before. Professor Emmet has come to have the same opinion as the result of his own further experience in the treatment of these tumors.

Pregnancy and Myomectomy.—In 1890 Professor Krolein removed a myomatous tumor weighing eight pounds from a young woman, who was at the time engaged to be married. Kronlein thought that in removing the tumor he had penetrated the uterine cavity. What he thought to be the uterine cavity, however, proved to be only a lymph space in the uterine tissue. Six months afterward the patient married and became pregnant after five months. Her pregnancy ran a normal course and labor came on in due time. The expulsive forces of the uterus proved insufficient and forceps had to be used, but a healthy living child was de-

livered, and there was normal delivery of the placenta, without unusual incidents. The rest of the puerperium proved normal. Quite a number of cases resembling Kronlein's have been reported to date. In Dr. West's own case nine incisions were made into the uterine muscle in order to remove fourteen myomatous tumors, and yet the uterus at labor proved to have perfectly normal expulsive force.

Types of Tumors.—When the myomatous tumors are encapsulated and form a distinct portion of tissue by themselves, they should be enucleated. When, however, the myomata are not definitely limited, but there is myomatous degeneration of large portions of the uterine muscle, the time for the removal should be put off as long as possible, using all ordinary methods of treatment. When symptoms become so severe that removal is absolutely indicated, then the uterus should be amputated, leaving the cervix and the ovaries untouched, if they are healthy, in all women who have not yet reached the menopause. These methods of treatment will save much suffering and will preserve internal functions in many cases, while in others it will at least not cause precocious menopause with its many annoying symptoms.

Accurate Diagnosis.—Dr. Bache McE. Emmet said that myomectomy demands above all things accurate diagnosis. Theoretically, it is easy to remove an encapsulated myomatous tumor, but it is not always so easy to determine exactly the pathological condition from which the woman is suffering. When there is extensive bleeding the cause should be determined. For this the important diagnostic point is the dilatation of the cervix by means of sponge-tents. The removal of myomata will not, however, always insure subsequent pregnancy. Often with fibroids there is adnexal disease present. Not infrequently also the tubes become affected as the result of the congestion in the genital tract.

Danger of Operation.—The danger of myomectomy is not as small as is sometimes asserted. The risk of secondary hemorrhage still remains and may prove fatal even under good conditions. In addition to this patients from whom myomata are removed sometimes suffer from edematous conditions that may lead to serious complications. There is in all cases a certain amount of danger that tumors will relapse. Not that the old tumors grow again, but where there has been adventitious material that has caused the development of one or more tumors there may prove to be embryonic collections of tissue that will develop further tumors after primary removal. Patients should not be given too much assurance that their condition will be absolutely cured by operation.

Selection of Cases.—Dr. W. Gill Wylie said that if the cases could be selected theoretically perfect results could be obtained. When one or more encapsulated tumors exist and the rest of the genital tract is absolutely healthy, there is no difficulty at all in removing the tumors. Usually, however, fibroid tumors are complicated by other serious conditions. As a rule, they give practically no symptoms of their presence until complications set in. Very few cases are suitable for myomectomy that give enough symptoms to make the patient willing to have it done.

Methods of Treatment.—In young women, as a rule, curetting will relieve a tendency to sterility quite as often as will myomectomy. The tumor should be removed if it threatens to be a source of danger, or productive of interference with the normal course of labor. Small myomata, however, may exist in the uterine wall and fail to enlarge during pregnancy. The pregnancy may proceed to a normal termination without the tumors interfering in the slightest bit with either its progress or culmination. An encapsulated myomatous tumor interferes no more with the uterine muscle than does the space produced by its removal.

Malignant Degeneration.—There is a certain amount of danger of fibroid tumors of the uterus becoming malignant. This danger is much more than is usually supposed, and many cancers in the body of the uterus have their origin in an old fibroid tumor. If fibroid tumors show any signs of activity in patients over forty, the whole uterus should be removed in order to avoid the danger of possible malignant degeneration.

Contra-Indications to Myomectomy.—Whenever there is chronic endometritis, especially if there is good reason to think it of gonorrheal origin, simple myomectomy should not be done, but the entire uterus should be removed. Gonorrheal endometritis is extremely obstinate in its course and practically resists all treatment. It may lead to peritonitis and its presence will keep up most of the symptoms from which the woman has been suffering before. There is a tradition that fibroid tumors will decrease after the menopause. It is always illusory to wait for this period in the hope that the tumors will decrease in size. The period of the menopause is an extremely dangerous one as regards cancer. There is an unsettled state of the involuting uterine tissues which easily predisposes them to malignant degeneration. The presence of a fibroid may easily prove the irritative stimulus that gives rise to malignant tumor. Fibroids and cancer it must be remembered often go together.

Senile Menstruation.—As a rule, if women menstruate after fifty, the supicion of the presence of a fibroid must be aroused. Sometimes this long persistence of menstruation is heredity. In certain families the persistence of menstruation for years after the usual climacteric is a well-known family trait. The recur-

rence of menstruation, however, after the usual cessation of the menopause has set in is pathognomonic of cancer in most cases and must, of course, be specially noted.

Comparative Radical Operation.—Dr. A. Palmer Dudley said that simple myomectomy is really a more radical operation than hysterectomy in the sense that it sometimes involves more danger and requires more careful technic. It is a serious thing to deliberately make a wound in a muscle richly supplied with blood and then, after simple suturing, drop this back into the abdominal cavity without instituting drainage. Recent experience, however, has shown that myomectomy can be performed without any added risk and to the evident advantage of the patient. Dr. Dudley's own experience in some few hundred cases is most encouraging and shows how much can be done of operative work on the uterus and yet allow the patient to retain all her functional capacity.

Contra-Indications to Myomectomy.—In Dr. Dudley's opinion myomectomy should not be performed in patients who are approaching the menopause. That is to say, as a rule, who are much over forty. It should not be done either in patients in whom there is a history of chronic gonorrhea. When gonorrheal endometritis with corresponding infection of the tubes and perhaps, also, of the ovaries, has developed it is almost futile to hope for any amelioration of symptoms except by radical removal of the uterus with the adnexa. Very often the symptoms will be found to be due to chronic gonorrheal infection rather than to the fibromyomata, in which case, needless to say, the removal of the tumors will not produce the promised amelioration of symptoms. Another contra-indication is the existence of recent syphilis. Here there is question whether the relief of the sterility and resulting conception will really be of benefit to the patient. The children are apt to suffer from the disease.

Social Status of Patients.—In the better class of patients, who are able to take every means to alleviate their symptoms and who may, if necessary, rest for long periods, the removal of myoma should not be suggested as early as in patients of the poorer classes, who have to work hard for their living, but to whom valetudinarianism is an impossibility. Myomectomy should not be done when, at the time of the operation, the uterus is found scarred and deformed as the result of the removal of other tumors. Hysterectomy is then the indication. When tumors are large, they may be taken away piecemeal and the uterus will gradually contract and prevent bleeding and also fill up the space that the tumor has occupied.

Operative Technic.—If in these operations the tubes are found to be patent, or whenever there is no sure indication of their closure, the surgeon has no right to remove them. As a rule, when fibroids are removed, drainage through the uterus by means of gauze is indicated. If it is feared that there will be considerable oozing, drainage may be made through Douglas's pouch. It is sometimes forgotten how easily this may be done without any subsequent inconvenience.

Operative Enthusiasm.—Dr. West in closing the discussion said that he pleads guilty of enthusiasm in the matter of conservative operation upon the adnexa of women. Some years ago it was not an unusual thing to see exhibited a perfectly healthy uterus that had been removed because of a small polypus that might easily have been taken out without disturbing the uterus itself. It is true that certain symptoms due to adnexal implication are usually noted in cases of myomata. These will, however, commonly disappear and the patient be restored to perfect health when the myoma is removed.

Myomata and Malignancy.—It has now grown to be an almost uniform belief that myomata do not develop into cancer, nor degenerate into any form of malignancy. The number of tumors in the case seems to mean nothing. In Dr. West's case sixteen tumors were removed, leaving nine scars, and yet labor was accomplished with almost absolute normality.

Vaginal Myomectomy.—Dr. Paul F. Mundé reported a case in which thirty-four myomata were removed by the vaginal route. In this case pregnancy followed myomectomy and the labor proved practically normal. It is probable that many of the operations for myomectomy, which are now done by the abdominal route, could be performed with just as much satisfaction through the vagina and without the added danger of certain post-operative inconveniences that are apt to follow the abdominal operation.

Hospital and Dispensary Mismanagement.—Dr. Thomas J. Hillis made some remarks additional to previous papers on the subject of the mismanagement of hospitals and dispensaries. This paper will appear in a subsequent issue of the Medical News.

Sickroom Bathtub.—Dr. Bellamy presented a model of a bathtub that can be used very handily in a sickroom in the treatment of such diseases as typhoid fever, in which full baths are required. There is no doubt that the bath treatment is essential in many cases of typhoid. Stewart of Montreal declares that many hemorrhages have their origin in the bathtub and that they are really due to trauma from heroic handling. The tension on the abdominal muscles during the time of lifting in and out of the tub causes the rupture of small arteries at the basis of the typhoid ulcers. Rest is important and this tub provides for it. The apparatus is on rubber wheels and may be brought to the side of the bed and an inclined plane is provided down, or up, which the patient may be gently moved to the tub. He rests here on a

perforated false bottom which can be raised to the top of the tub and then slowly lowered after the patient has been placed in it. The raising out of the tub is accomplished by means of this same false bottom.

Points in Bathing Technic.—The patients should not be plunged at once into water of uncomfortably low temperature. The first bath in typhoid should be given at a temperature not much below 100° F., the water being allowed to cool off gradually while the patient is in the tub. Instead of the shock that so often terrorizes patients, as the result of the first bath, there should be a positive feeling of comfort. After a time patients realize how much their feelings are improved by the bath and then they stand the preliminary shock of colder water much better.

Comfort of Typhoid Patients.—Attached to the bathing apparatus suggested by Dr. Bellamy, there is a force pump for bringing water to, or forcing it out, of the bathtub, in cases where the supply of water is at some little distance from the sickroom. It is important that a typhoid patient should have a comfortable bed. The more restful a patient is, the less danger of complications. There should therefore be either two mattresses or two beds for his use. He may easily be transferred from one bed to another, just after his bath, or during the bath the second mattress can be substituted for the first. The successful treatment of typhoid depends not on any special system of drug treatment, but on attention to minute details.

BOOK REVIEWS.

THE MUSHROOM BOOK. A Popular Guide to the Identification and Study of Our Commoner Fungi, with Special Emphasis on the Edible Varieties." By NINA L. MARSHALL. With many Illustrations in Color and Black and White. Photographed from Nature by J. A. and H. C. Anderson. Doubleday, Page & Co., New York.

THE fascinating glimpse that Mr. William Hamilton Gibson gave his readers, of the World of the Woods, reached its height when he brought out his Mushroom Book. It represented literally but a taste of what the woods would yield to the hungry, and of what literature would bring forth to satisfy inquiring minds. Since then there have been a number of mushroom books, some thoroughly scientific and satisfactory; others not so; but Doubleday, Page & Co. now bring out *the* Mushroom Book, with the most beautiful series of photographs taken from Nature in color and in black and white that have ever been published.

A very clear and simple text has been written around them, in which the technical difficulties of the fungus "lingo" have been reduced to plain, every-day words, so that anybody might be able to determine a common specimen, and get a very comprehensive knowledge of the most important families.

A certain familiarity with the fungi, especially with some of the deadly species that resemble the edible fungi, is becoming absolutely indispensable to physicians. People flock to the mountains and country side armed with the newest fad for recreation, of which mushroom hunting, with gustatory bent is one, and in spite of careful descriptions and plentiful illustrations the little knowledge often proves a dangerous thing. We therefore would advise physicians who are likely to practice in the vicinity of enthusiasts to get this last of the Doubleday series of Nature buds, and learn to distinguish good from evil in the mushroom world.

A SYSTEM OF PRACTICAL THERAPEUTICS. Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia. Second Edition. Vol. III. Lea Brothers & Co., Philadelphia and New York.

THE practical character of this system is nowhere more exemplified than in this third volume. It deals almost exclusively with surgical therapy —Anesthesia and Anesthetics, Surgical Technique, Fractures and Dislocations, Minor Surgery and Bandaging, Cerebral Concussion and Shock, Pleural Effusion and Empyema, Gangrene of the Lung, Peritonitis, Appendicitis, Abscess, Obstruction, Diseases of Rectum and Anus, Therapy of Genito-Urinary Tract in Male and Female, Therapy of Childbearing, Diseases of Eye, Ear, Nose and Throat from the Standpoint of the General Practitioner.

A glance at this condensed summary of the contents shows the every-day utility of the work and when it is added that each subject is considered by men of established reputations, who have had in mind the needs of the active worker in medicine, the practical character of the system needs no further comment.

MOSQUITOES. How They Live; How They Carry Disease; How They Are Classified; How They May Be Destroyed. By L. O. HOWARD, PH.D., Department of Agriculture. McClure, Phillips & Co., New York.

MOSQUITOES are in the air at the present time —both in the ambient and literary atmosphere. To bring them to earth, however, and to know their ways and how they may be rendered less obnoxious is the object of this admirable volume.

The author, as head of the Bureau of Entomology, is thoroughly *en rapport* with his subject and has breathed into its pages throughout the living breath of actual contact with the "critters." Most physicians know a few of the species to their discomfort; we recommend this work to those who would know more about them, especially those who would learn the ways of exterminating the pests.

BLOOD EXAMINATIONS AS AN AID TO SURGICAL DIAGNOSIS.[1]

BY JOSEPH C. BLOODGOOD, M.D.,
OF BALTIMORE, MD.

Shock and Hemorrhage.—Observations have demonstrated that there is a leucocytosis of 15,000 to 24,000 following hemorrhage. As a rule, this comes on within a few hours. There are not sufficient observations to demonstrate the relation between the amount of blood lost and the leucocyte-count. We have not sufficient data to clearly determine the exact changes in the number of white blood-cells in shock from injury alone without loss of blood.

Following hemorrhage, in addition to the rise in the number of leucocytes, there is a diminution in the number of red blood-cells and the percentage of hemoglobin. In severe hemorrhage a blood-count will indicate to a certain extent the amount of blood lost, but, as a rule, not until six or more hours have intervened after hemorrhage.

Examinations of the blood after contusion of the abdomen, to ascertain, if possible, whether we can distinguish by the changes in the elements of the blood the difference between shock from the injury alone, internal hemorrhages, and peritonitis from rupture, are not sufficient in number to allow any positive conclusions.

Cabot[2] writes: "Often one hears the question discussed in any accident-room in any hospital whether to operate at once or wait until the patient has got over the shock. The question is not often asked, far less answered, whether the shock is simple or largely anemic (cerebral or general) from loss of blood, or whether it is of nervous origin, *i. e.*, due to concussion or compression. The right decision of this question is of great importance, for if the shock means anemia transfusion may be indicated, while in a condition of cerebral concussion or compression transfusion will probably do harm." (Authorities do not agree with Cabot. Transfusion is not contra-indicated. See *Progressive Medicine*, December, 1900, p. 108.) "An examination of the blood enables us in certain cases to decide such a question—that is, if the number of red cells is considerably diminished (3,500,000 or less) and the patient is known not to have been previously anemic, the shock probably means hemorrhage." "The blood-count may enable us to gauge approximately the amount of hemorrhage. Here it should be remembered, however, that immediately after hemorrhage the count may be normal, since only the amount and not the quality of the blood is affected. Within a few hours, however, fluid is absorbed from the tissues into the vessels, and then an anemia will be indicated by the blood-count." "An internal or cerebral hemorrhage, a rupture of an extra-uterine pregnancy, ruptured aneurism, laceration of the spleen, kidney or liver, etc., can sometimes be diagnosed by the blood examination."

McLean,[3] in his article entitled "Examination of the Blood in Surgical Diseases," practically adds nothing new to Cabot's statement in regard to the blood examination in shock.

The Importance of a Careful Blood Examination Preliminary to General Anesthesia.—There are now sufficient observations to demonstrate pretty conclusively that in marked anemia, especially when the hemoblobin percentage is low, general anesthesia, especially if prolonged, is dangerous. Some authorities give 50 per cent., others 40 per cent., but the majority agree that 30 per cent. of hemoglobin is a danger signal, and, if possible, the operation should be delayed until appropriate treatment has been used to increase the percentage of hemoglobin and the number of red blood-cells.

This important subject has been studied by Cabot (*loc. cit.*), Da Costa, Mikulicz, Hamilton Fish,[4] and others.

My own experience[5] has been sufficient to indicate the truth of their statements. An anesthetic has great additional dangers when given to patients with the hemoglobin estimate below 50 per cent.

Post-Operative Leucocytosis.—There is need for much more study on this question. Most authorities agree that following ether there is *perhaps* a slight increase in the leucocytes, which, however, disappears within twenty-four and at most thirty-six hours. In operations with much loss of blood there would, of course, be a temporary rise in the leucocytes; but, on the whole, in the average operation one should expect the leucocytes to be within the normal limits—twenty-four hours after operation. If this is true, a sudden rise in the leucocytes would indicate some post-operative complication. In abdominal surgery it would suggest peritonitis, although if the peritonitis was a very grave infection the leucocytes would soon fall rapidly. Perhaps the leucocyte-count as an aid to the post-operative diagnosis in abdominal surgery is most certain in the early recognition of obstruction. Here there is always a rise, usually over 20,000, associated

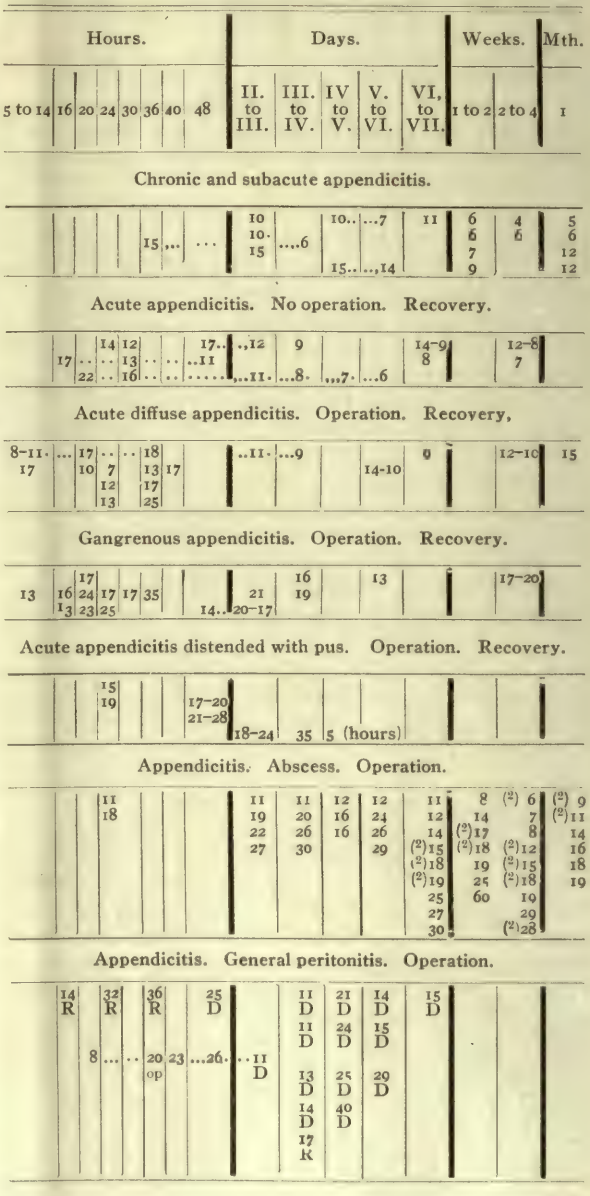
with any obstruction of the intestines. This rise generally takes place within from eight to twenty hours after the beginning of the obstruction, and in a few cases observed the rise in the leucocytes had been prominent before the clinical symptoms themselves were sufficiently clear to make a positive diagnosis. The number of observations so far have demonstrated that when, after laparotomy with general anesthesia, the patient develops slight distention, or even marked distention, with nausea and vomiting, which seems more or less due to paralysis of the intestines, and not to a definite obstruction or peritonitis, *the leucocytes do not rise,* at least not above 12,000 to 15,000. If these observations are confirmed the counting of the white blood-cells would be a great aid in the differential diagnosis in the first twenty-four to forty-eight hours or later, after laparotomy, between benign abdominal distention and obstruction or peritonitis, for which operative interference would be indicated early. This is apparently a closer relation between the extent and character of the operation and the post-operative leucocyte-count than the anesthetic. A more complete report on this is in preparation and will be published later.

Post-Operative Phlebitis.—In a few cases observed there is a rise in the leucocytes, varying from 15,000 to 20,000. Such a leucocytosis has been observed frequently in typhoid phlebitis; but, on the whole, the observations of the changes in the leucocytes after operation are not well established.

If the phlebitis is confined to the iliac veins the first symptoms are those of an acute abdominal lesion, viz., localized pain and slight muscle spasm in the iliac fossa, nausea and vomiting. If on the right side, after operation, the condition might simulate an appendicitis, or, in women, a salpingitis. In typhoid fever the early clinical picture is very much like intestinal perforation. A case of this character has been reported by Harvey Cushing[6]; also by William S. Thayer[7] in his article entitled "Observations of Blood in Typhoid Fever."

The Importance of the Leucocyte-Count in the Early Recognition of Acute Abdominal Lesions.—The discussion of this subject is the chief theme of this paper not only because of its importance, but, fortunately, in this field we have more observation.

Explanation of Table.—The following table represents all the counts made on cases of appendicitis. The first count in practically every instance was made when the patient was first admitted to the hospital, and this count is placed under the time corresponding to the number of hours or days since the beginning of the acute attack; subsequent counts (if made) are noted by dotted lines after the first count under the proper time. In the cases operated upon the last count represents the time of the operation, with one exception, in the group *appendicitis, general peritonitis, operation.* The letters Op. under the figure 20 represent the time of operation. The three subsequent counts are post-operative, and show the fall in the leucocytes, with general peritonitis. Under the column *appendicitis, abscess, operation,* there are only single counts. The figures 2 or 3 in front of the figures, representing the number of leucocytes, indicates that there were two or three cases with this number of leucocytes at this time. Under the column *appendicitis, general peritonitis, operation,* the letter R indicates the patient recovered, and D the patient dead. The time in these cases represents the entire interval of the acute attack, and not the duration of the peritonitis, which, in the majority of cases, was impossible to ascertain.



Leucocytosis in Appendicitis.—When observed within forty-eight hours the number of white blood-cells is in a majority of instances of great

[6] Johns Hopkins Hospital Bulletin, No. 92, November, 1898.
[7] Johns Hopkins Hospital Reports, Vol. VIII., 1900.

value, indicating the extent of the inflammatory condition of and about the appendix. This fact is well illustrated in the table.

Chronic and Subacute Appendicitis.—Sixteen counts. Here we have cases of recurrent appendicitis, or of appendicitis suffering from the first attack; first observed practically at the end of the attack, when the clinical symptoms were subsiding or practically over. The almost uniform, low leucocyte-counts, even in this small group of cases, are very suggestive that such an observation is an important additional aid to recognize that an acute attack of appendicitis is subsiding, or, when, seen later after the clinical signs have entirely disappeared, the distance of leucocytosis should be considered a distinct factor in excluding an abscess. It is noticed in the table that the highest count in this group of cases was 15,000. In one case, admitted thirty-six hours after the beginning of the attack, in which the local clinical symptoms were distinctly less according to the statement of the patient, and which when admitted were just sufficient to suggest an appendicitis, these slight local symptoms disappeared, asssociated with a fall in the leucocytes to 10,000 and 6,000. A later operation demonstrated a diffuse thickened appendix, but no pus. Observed between the second and seventh day the leucocyte-counts have been 15,000 in two cases, 10,000 in two cases, in one falling to 7,000, and in one case 11,000. *With but a few exceptions* these are distinctly lower counts than in the other groups of cases. In all of these cases, at an operation performed later, a simple diffuse appendicitis was found with no pus or evidence of infection outside of the appendix. In ten cases observed from one week to one month or longer after the last acute attack, in only two cases were the leucocytes as high as 12,000; the remainder were 9,000 and lower. In a majority of these cases there were no clinical symptoms; simply a history of one or more previous attacks. At the operation a diffuse appendicitis was found, with no evidence of pus outside of the appendix. Comparing this group with cases of appendicular abscess admitted from one week to one month or longer after the beginning of the attack (thirty-three cases) we see distinct differences. In those cases with abscess, only six out of the thirty-three cases had leucocyte-counts below 12,000. Some of these thirty-three cases of abscess exhibited no clinical evidence of tumor. This observation demonstrates that in cases of appendicitis admitted *late* in the attack a *high* leucocyte-count is almost a positive evidence of an *abscess,* even when the clinical symptoms have entirely subsided and the abdominal examination is negative. In a few cases, *but only a few,* we may expect to find a small localized abscess, even when white blood-cells show no marked increase; but this is a rare exception to the general rule.

Future observations may demonstrate that the leucocyte-count will aid us in indicating the better time to operate in cases of appendicitis with abscess. Many of these patients come to the hospital at the end of the attack, the clinical symptoms are subsiding or have ceased, and we usually find on abdominal palpation an area of tumor or induration, suggesting a localized collection of pus, which in some instances, however, proves to be a mass of adherent omentum. Now and then in such cases when we have delayed we have found that the localized pus has become much inspissated, and the virulence of the organism may have decreased. Experience would seem to demonstrate that if the pus is distinctly localized, and the symptoms on the decrease, it is, perhaps, the safer plan to delay the operation to a date when the difficulty of removing the appendix and the danger of infecting the general peritoneal cavity would be less. Our cases require a more minute study before such a conclusion can be demonstrated.

Acute Appendicitis; No Operation; Recovery.—In the cases admitted within forty-eight hours with acute symptoms, if on account of the clinical picture, operation has been delayed, we have always observed a falling leucocytosis. These patients have recovered, and at a later operation the appendix is found to be the seat of a diffuse inflammation, but there has been no evidence of pus outside the appendix. In one case admitted sixteen hours after the beginning of the attack the leucocytes fell in ten hours from 17,000 to 13,000, and in twenty-four hours to 11,000, associated with the disappearance of the symptoms. With one exception the highest first leucocyte-count in this group has been 17,000, falling in a few hours to 12,000, 9,000, or even lower. A patient admitted twenty hours after the beginning of the acute attack had a leucocytosis of 22,000. The clinical symptoms, however, were not very marked. The patient was observed eight hours. During this period the leucocytes fell to 16,000, and the local symptoms practically disappeared. Within the next twenty-four hours the leucocytes were 11,000, then 8,000, 7,000, then 6,000. Although this patient with a leucocytosis of 22,000 at the end of twenty hours recovered, and there is every reason to believe that the inflammatory condition about the appendix subsided, nevertheless it is an exception to the general rule, and it would be safer, I believe, to operate in those cases of acute appendicitis observed within the first forty-eight hours with a leucocytosis of 20,000.

Acute Diffuse Appendicitis; Operation; Recovery.—Eleven cases. The leucocyte-counts in this group of cases do not differ much from those in the group of acute appendicitis which were not operated on until after the end of the acute attack, and, of course, it is a question whether all of these cases might have recovered from this attack without operation. It is to be noted that in one case observed in the hospital the leucocytes rose from 8,000 to 18,000, and a second from 13,000 to 17,000. In *three cases* there was a fall in the leucocytes from 10,000 to 7,000, from 11,000 to 9,000, and from 14,000 to 10,000. In two cases observed at the end of two days and five days it was a question whether the patient

was getting over the attack or not, but it was considered wiser to operate. A simple diffuse appendicitis was found. In the third, admitted twenty hours after the beginning of the attack and observed four hours, the patient clinically was distinctly getting worse; the leucocytes had fallen from 10,000 to 7,000. The only high leucocyte-count in this group of cases was 25,000. This patient was seen thirty-six hours after the beginning of the attack, and clinically the attack seemed to be subsiding, but on account of the high leucocytosis it was considered best to operate. In this case the exudate about the thickened appendix was very excessive, and it is a question whether, if operation had been delayed, an abscess would not have developed.

The following two cases are reported in detail, the first because the patient was observed in the hospital from the beginning, and represents the typical rise in the leucocytes from 8,000 to 18,000 in thirty-six hours, associated with an acute diffuse appendicitis. It cannot be stated in this case whether the patient would not have recovered from this attack, but the rise in the leucocytes was a distinct aid in the early recognition of the disease, which was associated with but slight local symptoms.

The second case is reported in detail, because it represents the rare exception of a low and falling leucocytosis associated with a distinct increase in the local symptoms, in which case the operation was indicated chiefly on account of the increasing local signs, although a careful observation indicated a falling and a low leucocytosis.

Case I.—The patient, a girl, aged seven years, was admitted to the hospital with a rather indefinite history of previous attacks of pain and the history of pinworms in the stools. When first admitted and observed for seven days there were no symptoms. Suddenly, one night, she began to complain of abdominal colic, which, in a few hours, localized itself in the right iliac fossa; in six hours the leucocytes were 8,000; ten hours, 11,000; twenty-four hours, 17,000; thirty-six hours, 18,000. During this time the temperature rose from 98° to 100° F.; no nausea nor vomiting. The local symptoms consisted only of slight muscle spasm and tenderness in the right iliac fossa. The slight local abdominal symptoms, combined with the quite high leucocytosis, were considered sufficient to indicate an early operation. The appendix was free, but thickened by diffuse inflammation; the lumen of the appendix was filled with small pinworms.

Case II.—A colored man, aged about twenty years, entered the hospital with a history of diarrhea and colic of one week's duration, and of local symptoms; pain in the right fossa, suggesting appendicitis of twenty-four hours' duration. At first examination, temperature 104.2° F., pulse 99, respiration 30. The patient's expression was one of stupor; tongue coated, but moist; leucocytes 10,000. The abdominal symptoms were so slight that the possibility of typhoid fever was considered, and a Widal test made, which was suggestive, but not positive. I saw the patient four hours later. At this time the leucocytes had fallen to 7,000, and the temperature to 102° F.; but, on examination, the tenderness and muscle spasm in the right iliac fossa had slightly increased, and there was a distinct area of dulness in the right flank, which suggested encapsulated fluid. At the operation a diffusely thickened and inflamed appendix was found covered with a little fresh exudate, and there was some free, cloudy, sterile fluid in the abdominal cavity. The chief collection was retrocecal where the appendix was situated. After the operation the patient continued to have intermittent fever for a week, the cause of which we could not make out; there were no malarial organisms; the Widal reaction was not positive, and there was no leucocytosis. He made an uninterrupted recovery.

Gangrenous Appendicitis; Operation; Recovery.—In this group of cases, as a rule, the leucocytosis is higher and rises more rapidly, and in three instances it has been of the greatest importance in the early recognition of a grave inflammatory condition of the appendix, which, without doubt, would have led to general peritonitis and death if early operation had not been instituted. In one case the rapid rise in the leucocytes was practically the only clinical evidence of a grave abdominal condition. The patient, a boy, suffered from an attack of pain and nausea, and vomiting followed a few hours after taking a good deal of indigestible food. When the stomach relieved itself there was no further pain and no further abdominal symptoms. After twenty-four hours the leucocytes were 17,000. A leucocytosis of 17,000 in a patient a number of hours after taking food would make one suspicious of an inflammatory lesion. In thirty hours the leucocytes were 17,000, and in thirty-six hours 35,000. The highest temperature was 100° F. There were practically no abdominal symptoms, except the history of a short attack of colic and vomiting following indigestible food. Because of this rapid rise and the high leucocyte-count (35,000) it was considered safer to explore the abdomen. A gangrenous appendix with beginning purulent pelvic peritonitis was found. A second and almost similar case was observed when the leucocytes rose from 13,000 to 24,000 in twenty hours after the beginning of the first colicky pain, the first count being fourteen hours after the beginning of the pain. In this case there were, in addition, marked clinical signs of appendicitis. In the third case, with very slight local signs, the leucocytes rose rapidly from 13,000 to 23,000 in twenty hours (first count sixteen hours).

These three cases of gangrenous appendicitis I report in detail because they demonstrate the great diagnostic importance of the leucocyte-count:

Case I., observed by Dr. Thomas R. Brown in this city, communicated to me personally, is perhaps the most important. The patient, a boy, aged eleven years, indulged freely one Saturday

night about 8 o'clock in strawberry ice cream and soda water; at 4 o'clock the next morning he was awakened by severe epigastric colic, nausea, and vomiting. The patient was seen by Dr. Brown at 8 a.m. (four hours); temperature 98° F., pulse 76. He was given a seidlitz powder and powders of subnitrate of bismuth. The abdominal examination was negative. He was seen again at 10 a. m. (six hours); no change in the symptoms; no nausea or vomiting. At 6 p. m. (twelve hours) the temperature was 98.8° F., pulse 86. There had been a stool; the urine was voided without pain; he was apparently very comfortable, and complained of no pain; abdominal palpation was negative; he looked, however, a little languid. There was nothing in the clinical picture to suggest that the condition was anything more than that to be explained by indigestion. On Monday morning at 8 o'clock (twenty-eight hours after the attack of colic) his temperature was 99.4°., pulse 95. He had passed a comfortable night; no nausea or vomiting; no abdominal symptoms, but he looked a little more depressed. The leucocyte-count at this time was 17,000. (A leucocytosis twenty-eight hours after an attack of abdominal colic in a patient taking practically no food is an indication of some inflammatory condition.) At 11 o'clock the leucocyte-count was 17,500, temperature 100° F., pulse 100, but no abdominal signs. At 4 o'clock (thirty-six hours after the beginning of the colic) the leucocyte-count was 35,000, temperature 100.6° F., pulse 100. For the first time in the right iliac fossa there seemed to be a little swelling; no marked muscle spasm nor tenderness. He did not complain of pain when he voided urine. This rapid and high rise in leucocytes, even without abdominal symptoms, but following abdominal colic, was considered by Dr. Brown, his physician, and Dr. Finney, the consulting surgeon, a sufficient indication for exploration of the abdomen. On opening the abdomen an appendix eight inches in length and extending into the pelvis was found. The appendix was gangrenous for at least two-thirds of its length, and perforated at its tip; no adhesion, and no localization. The pelvis was filled with cloudy fluid; the intestines in the pelvis and right iliac fossa were injected, covered with a little fibrous exudate and cloudy fluid. Cultures were not taken. The patient recovered.

In this case the rise in leucocytes was practically the only indication for operation. There were no previous attacks of appendicitis, and the only clinical manifestations pointing to the appendix was the onset of the abdominal colic associated with nausea and vomiting.

Case II., recently observed by Dr. Mitchell and myself, resembles Dr. Brown's observation in the rapid rise in the leucocytes, but was associated in this instance with distinct abdominal symptoms. The patient, a boy, aged eighteen years, who also filled his stomach one Saturday night with indigestible food, experienced about six hours later intense abdominal colic, which was worse on the right side, followed in four hours by excessive nausea and vomiting. The abdominal colic continued all night and when he voided urine it gave him some pain. He walked to the hospital and was first examined about 1 p. m.; temperature 101° F., leucocytes 13,000. Both recti muscles were held tense, but the muscle rigidity was more marked on the right side. The clinical picture at this time was sufficient, without the leucocyte-count, to make a diagnosis of pelvic appendicitis. His parents were sent for at once, but refused operation until 6 p. m., so that he was not operated on until twenty hours after the beginning of the attack. He was first seen at fourteen hours. In fifteen hours the temperature was 102° F., pulse 112, respiration 28, leucocytes 15,600; in sixteen hours, leucocytes 16,000; in eighteen hours, temperature 104° F., pulse 112, respiration 28, leucocytes 19,000; in twenty hours, temperature 103.4° F., pulse 116, respiration 20, leucocytes 24,800. There had been no nausea or vomiting since the first attack at 1 o'clock the night before. The muscle rigidity and tenderness increased. At the operation a very long appendix was found situated in the pelvis, two-thirds of its distal end being gangrenous; no perforation. The pelvis and the lower portion of the abdominal cavity were filled with cloudy fluid. The intestines in the pelvis were injected. Cultures: Bacilli, but no streptococci. The patient made an uninterrupted recovery.

Case III. was observed in the hospital. The patient, one of the hospital residents, aged twenty-eight years, was taken with abdominal colic and slight diarrhea, a condition not uncommon with the residents during the hot summer months. At the end of sixteen hours the temperature was 101° F., leucocytes 13,000. There was no distinct muscle spasm, but a slight area of tenderness on deep palpation at the outer border of the right rectus muscle; no nausea nor vomiting. Also about this time micturition gave a little pain. At the end of twenty hours the temperature was 101.6° F., leucocytes 23,000. The patient vomited for the first time. The patient was immediately prepared for operation, which was performed twenty-two hours after the beginning of the attack. The temperature just before the operation was 104.2° F., pulse 80, and for the first time during the preparation for operation muscle spasm was noted. At the operation by Prof. Halsted the entire appendix was gangrenous and situated in the pelvis; in its center over one hard concretion the wall was very thin; the pelvis was filled with cloudy fluid containing the bacillus coli communis. The patient recovered.

Acute Appendicitis Distended with Pus; Operation; Recovery.—There are five cases in this group. In all the localized symptoms were sufficient to indicate immediate operation, due, perhaps, to the great tension of the thickened and inflamed appendix, which was distended with pus, but not yet gangrenous. Such a condition is one of great danger, because an appendix distended with purulent material containing, without much

doubt, bacteria of great virulence, might perforate at any moment and discharge into an unprotected peritoneal cavity. Fortunately, in these five cases the operation was performed in time. Two cases were admitted twenty-four hours after the attack. In one the leucocytes were 15,000; in the other, 19,000. The local signs in the patient in whom the leucocyte-count was only 15,000 was less marked, the pus in the appendix was of smaller quantity, the walls of the appendix thickened and under less tension. What would have happened if observed a number of hours longer is difficult to tell. Two cases were admitted forty-eight hours after the beginning of the attack, one with a leucocyte-count of 17,000, with a second count in two hours, just before the operation, of 20,000; the other of 21,000, second count of 28,000. A third case, admitted on the second day, observed five hours showed a rising leucocyte-count from 18,000 to 35,000. In these three cases the clinical picture was a marked one, and the appendix was not much thickened, but was under great tension. In only one of these five cases was there a walling off of the appendix by peritoneal exudate, and it seems fair to infer that a perforation would have been followed by a very virulent and perhaps fatal peritonitis.

Appendicitis; General Peritonitis; Operation.—The correct interpretation of the leucocyte-count in this group of cases is difficult, because in the majority of cases it is hard to estimate the duration of the peritonitis. Observation seems to demonstrate that in the early hours of peritonitis there is a rapid rise in the leucocytes, which, however, soon falls. These cases have been grouped according to the duration of the attack, and not to the approximate duration of the peritonitis. Five cases have been observed, in each of which the beginning of the attack was within forty-eight hours. Three cases recovered—one, operated on sixteen hours after the beginning of the attack, with a leucocytosis of 14,000; one, twenty-four hours, with a leucocytosis of 32,000; and one thirty-six hours, with a leucocytosis of 36,000. In these three cases there were distinct local symptoms, but slight general abdominal symptoms. There was no distention of the intestine; the exudate was chiefly purulent; in the exudate in the general peritoneal cavity only the colon bacilli were found, and no streptococci. In one case, observed forty-eight hours after the beginning of the attack and operated on at once, the leucocyte-count was 25,000. The general abdominal symptoms masked the local symptoms, the patient was very ill, the intestines were distended, streptococci were present, and the patient died. One patient was observed in the hospital. Twenty hours after the beginning of slight abdominal colic and pain, localized in the right iliac fossa, the leucocytes were 8,000; sixteen hours later, or thirty-six hours after the beginning of the attack, the leucocytes were 20,000. Clinically, the patient was not very ill, but on account of the rise of the leucocytes from 8,000 to 20,000, operation was performed. The appendix was perforated and surrounded by a few drams of purulent material. This pus was not walled off by adhesions; the general peritoneum was slightly injected; it appeared as if there was beginning general peritonitis. After the operation the leucocytes continued to rise for twelve hours up to 26,000; then within the next twelve hours fell to 11,000, the patient dying with a clinical picture of peritonitis, which was found at autopsy. In this case streptococci were present. In five cases admitted three days after the onset the symptoms, all showing the clinical picture of peritonitis, the leucocyte-counts in four were 11,000, 11,000, 13,000, and 14,000. These four cases were fatal. The fifth case, whose leucocyte-count was highest (17,000), recovered. The cultures from the peritoneal cavity in this case showed bacillus coli communis.

These counts and others not given in this short paper seem to demonstrate that within forty-eight hours after the beginning of an attack a very high leucocytosis is suggestive—but not at all positive—of beginning peritonitis, and that the leucocyte-count does not help us with regard to prognosis. After the second day, in cases in which the peritonitis has been present longer, we have never observed a recovery with a low leucocyte-count. If the leucocytosis still remains high at this period the prognosis seems better for the ultimate recovery after operation.

Appendicitis; Abscess.—So far, in our observations, we have but two cases of abscess with leucocyte-counts observed within forty-eight hours after the beginning of the attack. In one the leucocytosis was 18,000, and there were distinct local signs, although, on account of the muscle spasm, it was impossible to make out a collection of pus. This patient was operated on twenty-four hours after the beginning of the attack. A small abscess was found about the perforated appendix; the collection of pus was well walled off, but there was beginning peritonitis demonstrated by cloudy sterile fluid and fibrinous exudate on the intestines about the abscess. The patient recovered. The low count—11,000—twenty-four hours after the onset is hard to explain. This patient had marked local signs of inflammation, but no definite tumor. At operation there was evidence that there had been recurrent attacks; the adhesions about the appendix were very firm, but the collection of pus was very small. The patient recovered.

There have been twenty-seven cases of appendicitis with abscess between the second and seventh day. In six cases the leucocyte-counts have been between 11,000 and 12,000; the others higher, the majority between 18,000 and 30,000. The interpretation of the leucocytes at this stage of the disease, especially between the third and seventh day, is a difficult one. A high leucocytosis after the second day of the disease, in the majority of instances, is an indication of gangrene, pus in the appendix, abscess, or peritonitis. A low leucocytosis has been associated with an

acute attack, getting well or completely over, but in a few instances it has been associated with abscess and peritonitis. In these six cases of abscess, with leucocyte-counts between 11,000 and 12,000, four were distinctly getting well, the abscess well walled off; in two the patients were very ill, and there was evidence of beginning peritonitis; one died.

The interpretation of the leucocytosis in the cases of appendicular abscess between one week and one month has already been discussed with the group of cases of chronic and subacute appendicitis.

Conclusions in Regard to the Interpretation of the Leucocyte-Count in Appendicitis.—Although there are exceptions to the rule, a rising leucocytosis is an indication for an operation. In the majority of instances, if the leucocytes reach 18,000 before forty-eight hours, it has been an indication of an advanced pathological lesion. For example, excessive exudate with a diffuse appendicitis, gangrene, or an appendix distended with pus, abscess, or beginning peritonitis. When the leucocytes have been below 18,000, or, when counted a number of times, have fallen in number, the patients have recovered without operation. With a fall in the leucocytes there has been associated a rapid cessation of the local symptoms, or, if operated on, the appendix has been the seat of but slight diffuse inflammation.

Observed later in the attack, especially after the fourth day, a high leucocytosis has usually been associated with localized abscess or beginning peritonitis. It is to be remembered, however, that it is possible to have an abscess with a low leucocyte-count. Out of the fifty-six cases of appendicitis with abscess fourteen have had a leucocyte-count between 6,000 and 12,000; the remainder have been higher, the majority over 20,000; the usual count is between 20,000 and 25,000, one count 30,000, one 60,000.

It is also to be remembered that with peritonitis there may be a very low leucocyte-count. This, so far in our observations, has been associated with an extreme septic condition of the patient, and in every case death has followed. These low leucocyte-counts have been observed in patients admitted to the hospital three days or longer after the beginning of the attack, so it is difficult to ascertain the exact duration of the peritonitis. Observations are sufficient to indicate that in the majority of instances beginning peritonitis is associated with the rise in the leucocytes, which, however, falls as the patient becomes more septic.

In a general way we may feel that a patient admitted with symptoms of peritonitis, with a high leucocyte-count, has better chance for recovery. The leucocyte-count simply indicates, however, a short duration of the peritonitis. The positive prognosis depends more upon the bacteriological findings than upon the leucocytosis. So far in our observations in the four cases which recovered the cultures demonstrated the presence of colon bacilli and other bacilli, but no streptococci.

Before more definite conclusions can be made in regard to the interpretation of leucocytosis in appendicitis we must have more observations, especially observations of cases from the beginning of the attack, where we have a number of counts. There are sufficient observations, however, to make a careful surgeon insist upon a blood-count in every case of acute abdominal lesion, and during the first forty-eight hours to have counts made every four to six hours. *A rapid rise in the leucocytes, especially above 18,000, should, in my opinion, be a sufficient indication for exploration, even in those cases in which the local symptoms are very slight. In the few exceptions in which the local symptoms are sufficiently distinct to indicate an operation a low leucocytosis should not influence as to delay operation.*

Leucocytosis in Intestinal Obstruction.—Dr. Harvey Cushing, I think, was the first in this country to call attention to the leucocytosis associated with intestinal obstruction. I referred to this in *Johns Hopkins Hospital Reports*, Vol. VII., 1898, p. 332, in relation to leucocytosis in strangulated hernia. Since Cushing's first count in August, 1898, the leucocytes have been estimated in almost every case of intestinal obstruction, and in this group of cases the increase in the number of white cells associated even with very slight symptoms of intestinal obstruction has been found to be of great value in the early recognition of the obstruction, frequently before the clinical signs were positive. We have a large group of cases which have demonstrated that within twelve hours after the beginning of the obstruction the leucocyte-count may rise to 20.000. Within the first twelve to twenty-four hours a few observations would demonstrate that if the leucocyte-count rises above 25,000 or 30,000 the probabilities are that one will find gangrene of the obstructed loop or beginning peritonitis. If observed on the second or third day after the beginning of the symptoms it is difficult to make a differential diagnosis with regard to gangrene or peritonitis. After the third day, in cases in which there is no gangrene and no peritonitis, or in which the auto-intoxication is not yet very grave, the leucocytes still remain high—15,000 to 23,000, according to the degree of obstruction—complete, higher; partial, lower. In the presence of gangrene, peritonitis or grave auto-infection, the leucocytes begin to fall. If the patient is admitted after the third or fourth day with a history of intestinal obstruction, and still has a high leucocyte-count, the prognosis is good for operation. If the count is low, and especially if it is below 10,000, the probabilities are that you will find at operation extensive gangrene or peritonitis, or the patient will be so depressed by the auto-intoxication that reaction does not follow relief of the obstruction.

In five cases of strangulated hernia admitted within twelve hours after the rupture had become irreducible the leucocyte-counts were 10,000, 15,000, 18,000, and in two cases 20,000. In all of

these cases the sac contained congested intestine. All the cases recovered after operation. In the one in which the leucocytosis was 20,000 we were able to reduce the rupture with ice bags, the leucocytes falling in three hours to 18,000, and in twenty-four hours to 12,000. In one case the patient left home with an irreducible hernia of some hours' duration, but during the journey of some fourteen hours on a railroad train the rupture became reduced, and on admission the leucocyte-count was but 6,000, which seemed to exclude the possibility of reduction *en bloc* of the rupture. The patient recovered, and some days later was operated on for the reducible hernia.

An observation of my own demonstrates the importance of even a slight rise in the leucocytes as an aid to early recognition of obstruction. The patient had recently been operated on in the hospital for acute appendicitis with abscess, and the wound had been drained. This clinical history, of course, pointed to the possibility of obstruction from adhesions. Some four months after this operation he came to the hospital complaining of abdominal pain of six hours' duration in the region of the scar. There had been no nausea or vomiting, and abdominal examination was negative. The pain, however, was quite severe and was slightly remittent, as if coincident with peristaltic action, although such intestinal movements could not be made out during a long and careful examination. The leucocyte-count in four hours rose from 8,000 to 12,000. There was no fever, and the patient had not taken any food.

In view of the history and rise of the leucocytes an exploratory operation was done. It was found that the omentum and cecum were adherent to the old wound, and to the cecum a knuckle of small intestine was adherent, producing a partial obstruction. The ileum from this point of obstruction for a distance of one foot was collapsed; in the other direction slightly distended. The operation required some time in order to separate all the adhesions and it was fortunate that an early exploration was done, when the patient was in such a good condition that prolonged anesthesia was not contra-indicated.

The Leucocyte-Counts in Cholecystitis.

Acute Cholecystitis.—In seven cases the leucocyte-counts have varied from 20,000 to 26,000. Two cases admitted at the end of the attack, with no symptoms, had leucocyte-counts of 8,000. The rise in the leucocytes associated with symptoms of acute cholecystitis does not seem to demand the same imperative early operation as similar counts associated with symptoms of appendicitis, because here the danger of peritonitis or abscess is a very distant one. We have observed two cases from the very onset in the hospital. One case was of special interest because the cholecystitis occurred during convalescence from typhoid fever.

The patient, a woman, aged forty-nine years, was admitted to the medical side, apparently at about the tenth day of typhoid fever; the leucocyte-count was 6,000. During the forty-two days she had a more or less uninterrupted typical typhoid attack, with no rise in leucocytes. On this day (the forty-second), at 4 o'clock in the morning, the temperature, which had been normal for some days, rose to 101.7° F., and in four hours to 105.2° F. The patient complained of pain in the abdomen and region of the gall-bladder. In this area there was distinct muscle spasm, but, on account of the muscle spasm, no tumor could be made out; respiration 56, pulse 128; the leucocytes had risen to 16,500; in three hours to 22,000. The operation was performed at this time by Cushing. Five hours after the beginning of the attack the gall-bladder contained gall-stones and slightly purulent bile; cultures, the bacilli coli communis.

The second case was rather a feeble man, aged sixty-five years, who on November 3,1899, under ether anesthesia had been operated on for a very huge lipoma of the thigh; following the operation pneumonia associated with a high leucocytosis. For some days the temperature had been normal, with no leucocytosis. On the 15th, in the morning, he complained of abdominal pain in the gall-bladder region, slight nausea, and vomiting. Examination of the abdomen was negative. This attack of pain lasted a few hours and then disappeared; temperature 100° F., pulse 99. During the afternoon he had slight attacks of pain. The next morning, twenty-four after the first gall-bladder colic, associated with pain, the temperature rose to 102° F., in a few hours to 103° F.; leucocytes 13,000. In the gall-bladder area there was distinct tenderness and muscle spasm, and on deep palpation one felt a tumor descending on inspiration. The leucocytes rose from 13,000 to 22,000 in six hours. There were no signs of pneumonia or of malaria; clinically the picture was that of acute cholecystitis. The operation was performed under cocaine anesthesia. The gall-bladder was distended and contained purulent material and a few gall-stones. The cultures showed bacillus coli communis and staphylococcus pyogenes aureus. The patient recovered.

THE RACIAL FACTOR IN HYSTERIA.[1]

BY JULIUS ULLMAN, M.D.,

OF BUFFALO;

INSTRUCTOR OF CLINICAL MEDICINE, UNIVERSITY OF BUFFALO; ATTENDING PHYSICIAN TO THE GERMAN HOSPITAL.

BEFORE discussing the racial factor in hysteria, it is my desire to make a few general remarks concerning hysteria in its broader sense. This disease, ever coming to our attention by the very accuracy with which it was simulate organic nerve diseases, is confined to no latitude, country or people, and if we would use comparative methods of studying it we might find well-authenticated examples of its existence as noted by competent observers in the lower animals.

M. Aruch, an instructor of veterinary surgery at Milan, has reported three interesting cases of

[1] Read before the Medical Section of the Buffalo Academy of Medicine.

hysteria occurring in the dog. The first, an affectionate, intelligent female dog, became moody because a baby was born in the family of the master. There developed dysphagia, polyuria, a capricious humor, an alteration of the voice (aphonia), and progressive paralysis of the legs. There was anesthesia, but no atrophy. The dog was given nux vomica and died in convulsions, but on autopsy no lesion was found in the nerve centers. The second case was that of a dog, eleven years old, domesticated, affectionate and intelligent. He developed convulsions, without the loss of consciousness, occasioned by the master scolding him. Since the first attack he was subject to the same attacks every time the master entered the house. The third case was that of a bull-terrier, two years old, which previously had a paraplegia of which he had been cured for over a year. His mistress procured a companion bitch and afterward the dog lost appetite and gaiety. There developed dysphagia without loss of either bladder or rectum function. The dog was cured by a separation from the companion dog.

Hegier recently has also described very good examples of hysteria in the lower animals. The first case was that of a kitten which was bitten in the back by a dog and at once became paralyzed. When seen by the author five or six weeks later, it moved the forelegs, but dragged the hind ones. The hind legs and the posterior third of the trunk on the ventral dorsal and lateral aspect were completely anesthetic. The tail also was paralyzed. The rectum and the bladder were not affected, however. A servant, desiring to test the fallibility of the saying that a cat possessed nine lives, threw the kitten from the window to the pavement below where it alighted on all four and ran away. It was permanently cured of a paralysis which had lasted two months. The second case was that of a canary, which had been much frightened and shocked by reason of seeing a cat attempting to get into its cage, became aphonic for a number of months, after which it sang again.

Concerning hysteria in the human species, it does not belong to any one time. Although the word "hysteria" does not occur in the Bible, it must certainly have been entertained there, and in the New Testament in which are recorded so many allusions to the miracles performed by the Nazarine, in the light of our present knowledge we believe that hysteria must then have existed. The Greek derivation of the word hysteria, meaning a morbid condition having its seat in the uterus, leads us to the belief that the Greeks must have known much of this affection, and it is a curious fact that for nearly two thousand years the idea was prevalent that the uterus was the seat. This was entertained by Hippocrates, Plato, Galen and even up to Sydenham's and later Charcot's time. It shows that during this time it was most seen in the female and this fact present statistics also verify. It was common in Sydenham's day and in Cromwell's time, but many disorders no longer considered belonging to this disease were mentioned.

There are certain etiologic factors, classified by Gilles de la Tourette, which if allowed to play a rôle will overwhelm the individual and will cause definite symptoms of hysteria to appear in any race be it Caucasian, Mongolian, American, Ethiopian or Malayan.

1. (*a*) Influences of the emotions, including moral passions, such as disappointment, anger; (*b*) influences of education, a higher civilization being conducive to the disease; (*c*) religion, with its furors and frenzies.

2. Traumatism, physical and mental; the traumatic neuroses of the Germans.

3. General diseases, typhoid, pneumonia, scarlatina, tuberculosis, grip, rheumatism, diabetes mellitus, malaria, syphilis and chlorosis.

4. Influence of the sexual organs; as the term implies, the uterus was supposed to be the seat, but, as Charcot later showed, the ovaries seem to be a factor also.

5. Influence of intoxications, lead, alcohol, mercury, sulphur, carbon, and tobacco. The effects of chloroform, ether, morphine, and lastly ptomains.

From the above classification we note that there are two factors, the physical and the psychological. The psychological factor is very important in hysteria, and is in fact dependent upon the physical condition of the individual. As an example we often see hysterical phenomena in those suffering from anemia and auto-intoxication of phthisis, or the physical traumatism in producing the traumatic neuroses of hysteria. Here the physical injury is also accompanied by the psychical insult.

If we are then to consider a racial factor in this disease, we must study the emotions, temperament, surroundings and habits of the race or nation, all of which are referable to their history and civilization.

Hysteria is almost unknown in the savage and barbarous states, but, as Féré says, in the less cultured races where fear, superstition, and a tendency to immitation are seen under their most primitive forms, hysteria is often encountered in epidemics. The savages of our own time, as will be shown later, reproduce the strange scenes which were so frequently seen in Europe during the Middle Ages, namely the dances of Saint Guy in Luxemburg.

In ancient times, and even now among the savage tribes of Africa, if a nation or tribe were conquered, little heed was given to the personal feelings of the subjected. In Rome the prisoners were led captives by the conquering host. They were jeered, scorned, beaten, and led into slavery. Was not this treatment indelibly written upon their higher psychical beings, and are not there many to-day bearing the effects of the ill treatment of their progenitors?

De la Tourette states that all races are subject to the disease, and among the Caucasian race the Israelite gives proportionally the largest number. M. Raymond states that in Warsaw, Poland, mas-

culine and feminine hysteria is common and most frequently encountered among the Israelites. In Europe it is seen as well in Finland as in the islands of the Mediterranean, and among the nations it is seen more in Russia and France than among the Germans and English. The national temperament must, therefore, also be a factor, as well as the social and political conditions.

The Jew in Europe and more especially in Poland and Russia is, as already stated, very liable to hysteria. Let us analyze, if possible, the cause. The Jew has always shown a fertile mentality. He was the writer and transcriber for all times. He translated from Hebrew to Arabic, Greek, and Latin. The most esteemed and most despised of all races, now enjoying a golden era of peace and happiness, then suffering the greatest oppression and persecution, becoming but the chattels of those inferior in intellect and morals. Numerically weak, and isolated, he could not physically take up the gauntlet and strike back the oppressor. Denied the privilege of travel, heavily burdened with taxes, shut up in the ill-ventilated ghettos, excluded from trades and professions, their physical sufferings were great, but their mental sufferings were greater.

The religion of the Jew does not allow his intermarriage with the Gentile. The laws of the Middle Ages did not allow a free interchange of this people, and marriages were not only entered in among the same people, but between near relatives, cousins, nephew and aunt, niece and uncle, etc.; so we have added to other causes the element of consanguineous marriages in production of hysteria. It being easily simulated, hysteria was contagious to the Jew thus restricted. The present generation of Jews, although in some countries, as in America, little persecuted, shows the stigmata of this disease because of the sufferings of their ancestors. It has then been transmitted by heredity in the sense that the child may learn to simulate or imitate the disease from the parent, usually the mother. In European countries, namely, Russo-Poland, Galicia, Roumania, Servia and Bulgaria, where religious tolerance is not enjoyed and where persecution and oppression are common, the Jew is markedly hysterical, and therefore in this country we find hysteria more common in the recently emigrated and especially from those countries where they are most persecuted.

Those who have visited the foreign cities have seen the patriarchal Jew. He is not unknown in our larger cities. Denied the education of the State schools, he has learned from the Rabbi in the dimly lighted and poorly ventilated schoolroom, to interpret the Talmud and mourns and bemoans the destruction of his Jerusalem. Despised, hoping in vain with a sturdy faith, reading of the grandeur of his ancestors, and comparing his present sordid lot have made an impression on him, which if you doubt is only verified by looking at the physiognomy of the Russo-Polish or Galician Jew of to-day—a Semitic feature with a ghetto expression. Prof. Kraus describes a peculiar type of Jew called the "Juif errant," a peculiar, rather hopeless individual who wanders over Europe from neurological clinic to neurological clinic. He often has a grave form of hysteria. In Kraft-Ebing's clinic at Vienna there was a good example of this type of Jew who suffered from astasia-abasia. It would be indeed surprising to us if these unceasing persecutions through periods of centuries should not have had their effect upon this people. It was not of short duration, but a continuous oppression, and in this regard they have suffered mental tortures as no other people in history.

From the German point of view the Latin race is to be regarded as hysterical. The Slav is also considered very hysterical. This is also to be attributed to his condition of serfdom.

Unlike the continued exciting causes which have existed to make hysteria and other nervous diseases frequent among the Israelites, there are conditions which give rise to epidemics of this disorder. The religious furors have affected many races and peoples, but from this the Jew seems to have been free. I allude again to the St. Guy's dance of Luxemburg where the hopping became contagious and the entire community was affected. The same may be said of people less civilized, as shown by the snake dances of the Indians, and the weird dances of the Dervishes.

Witchcraftery is based on superstition and religion. It is based upon a hysterical background and, though fortunately of the past, may still occasionally be seen in the ignorant lower classes and among the savage blacks of Africa. It apparently had its origin in Germany and was of three degrees as follows: (1) Man renounced God and went over to the devil offering an oath of allegiance; this was the method of witches; or (2) the devil took possession of the man during life converting him into one possessed; or (3) man might make a compact of mutual obligation, assigning his soul to the devil.

In 1484 to 1492 there was a wholesale burning of witches, and it continued well until the eighteenth century. Religion, so outrageously abused by the clergy who invariably were inquisitors (and as each inquisitor received a fee for every witch convicted, there is no wonder that there was so many accusations), the trial of witches was carried on against poor cracked-brain creatures (demomaniacs). Many of those supposed to be possessed must certainly have had the stigmata of hysteria, for, as Féré says, undoubtedly hysterical anesthesias held the first place among the marks of the devil.

In England witchcraftery was made a capital offense by statute of Queen Eliazbeth in 1562, and between 1640-1644 there were 3,000 legal executions. When the Puritans came to this country to escape their religious oppressions, they brought with them seeds and culture-ground of a psychological conditions which made the Salem witchcraftery possible.

As atavistic tendencies may slumber for generations only to rise in some future day under some other guise and in more resplendent garb, so we of to-day are not surprised that in that same New England, among the progeny of believers in witchcraft, there should arise from the ashes of a hopeless delusion another manifestation of a religious furor, hysterical in nature, but garbed in more alluring and inviting foliage, but nevertheless just as delusory and subject to a similar end, namely, Christian science.

In studying the black race we must go first to Africa. They are found in a wild and savage state, superstitious, living in tribes, each with its chief. Their religious belief was filled with superstitions; no evil occurred but was the work of some malignant spirit, and because of their belief, like more civilized communities, they devised charms and amulets. Witchcraft was common. Those accused were tortured and often buried alive, or underwent tortures of ordeal from which if they survived they were free from the evil spirit. The natural temperament of the negro is emotional. As Booker Washington aptly remarked, the negro, unlike other emigrants who came to this country, had the advantage of having his passage paid, but the horrors of that frightful journey across the high seas in the slave ships, so admirably described by Spears (*Scribner's Magazine,* Aug. and Sept., Oct., 1900), like the persecution of the Jews must have left indelibly impressed a psychical trauma which has been transmitted to the negro of the slavery days, and in a lesser sense to the generation following the emancipation.

Although Hammond says that hysteria was almost unknown during the slave period, May strongly contradicts this assertion, for he found the most typical cases of hysteria in the negro during religious excitement and these scenes were very common during slave time. The statistics of hysteria among the negro are very difficult to obtain. There can be no doubt that it manifests itself very frequently in the religious excitement attending revival meetings. It is frequent among Hottentot women of the Cape and in Abyssinia. Retourgeon of Brazil has seen it among the children of slaves, and very frequently among half breeds. In hospital work it is occasionally seen among the females. In order to obtain a better knowledge from those who have seen many negroes, I addressed letters of inquiry to Drs. Shadd and Revburn of Washington, Dr. Daniel Williams of Chicago, and Drs. Osler and Thomas of Baltimore, and from answers received from these gentlemen am inclined to believe that the negro is as subject to hysteria as the white man with the same intelligence, education and environment. It is more frequently seen in the mulattoes and also in the descendants of slaves, and less in the illiterate than in the more civilized.

The Indian is supposedly the first inhabitant found here by the settlers. They lived a foraging life, like other primitive and savage people, their beliefs were full of superstition. Many of their superstitious rites were accompanied by undoubted hysterical seizures and manifestations which resembled those of the Middle Ages (St. Guy's dance).

Dr. Charles Buchanan, a physician who has had much experience among the Indians at the Tulalip Indian Agency in the State of Washington, writes me of a quasi-religious, quasi-medical sect or cult of Indians, peculiar to Puget Sound, termed the Shakers, which sect, according to the writer, represents the aboriginal idea of Christian science. Unless through their superstitions they became imbued by a religious furor which became epidemic, few individual cases of hysteria were noted. It would seem that the squaw, who in reality was regarded as the beast of burden, should have become hysterical, but the many cases in which the parturient woman isolated herself a week before and a week after labor, with absolutely no other care or attention than she could bestow upon herself, would certainly disprove the above statement.

We can, therefore, say that individual cases of hysteria could not have been common to the Aborigines until the pioneer settlers, as an advance guard of civilization, commenced the benevolent assimilation and taught the Indian much of the good, but more of the vices of the civilization then extant. We have previously referred to the effects of alcohol as an exciting cause of this disease and see an excellent example of its effects in the deterioration of the American race, physically and morally, so much so that the Government has had to enact laws prohibiting, under a penalty of fine and imprisonment, the sale of any liquors to Indians. As the Indian becomes more and more civilized, he becomes more subject to the disease, for education conduces to a larger occurrence of hysterical manifestations. Dr. A. D. Lake, physician to the Thomas Asylum for Indians, situated in the Cattaraugus Reservation, near Gowanda, N. Y., has observed the Indians of this State for twenty-five years. In his earlier acquaintance with them the disease was unknown, but in the past ten years he has frequently seen both neurasthenia and hysteria. They seem to characterize themselves among the Indian, especially among the girls, in some of whom he has seen convulsions, but often in the manifestation of a moral perversion. No other reason can be assigned for the production of this disease among the Indians than in the change which civilization has procured in their habits and mode of life.

As yet I have not been able to ascertain much concerning the frequency of hysteria among the Chinese, but I do not believe that it is very frequent. Hirsch states that Hindoo women are not much disposed to hysteria, but that the European races living in Hindoostan are as much disposed to the disease as those resident in European countries.

We have, therefore, come to the conclusion that hysteria is seen among all people and in all countries, and the fact that it affects certain races

more often than others, like the Jewish and the Latin races, may be attributed to causes of environment rather than inherent qualities of a race. Heredity plays a rôle only in that the child may learn to imitate certain traits of its parent, the environments and habits remaining the same.

In conclusion we must not forget the hysterical background which may be an epiphenomenon in certain organic diseases, in certain races such as the Slav, Latin, Israelite, nor, on the other hand, to slight the fact that, though symptoms of hysteria are well marked, as they usually are among Russo-Polish women, they may at the same time be suffering from organic disease.

Better therapeutic results will therefore often be obtained among the susceptible races, or those in which hysteria is most common, by drugs, suggestion and mechanical means of treatment directed against a latent hysterical condition in addition to treatment for organic disease if it be present.

THE DRUG HABIT; ITS CAUSE AND RESTRICTION.[1]

BY JOSEPH M. AIKIN, M.D.,
OF OMAHA, NEBRASKA.

NEXT to alcohol, as a poison to the nervous system in common use, stands opium with its derivatives, especially morphine. This most useful and very efficient drug for relief from pain is likewise a most fruitful cause of relentless physical and mental suffering.

The effects of the poppy, when introduced into the human body, have been in vogue and utilized for many centuries, but the subcutaneous use of morphine was not known until the middle of the past century and but sparingly used until the great body of physicians now in actual practice began their medical career. The oriental nations used the crude preparations of the poppy plant among all classes as a source of pleasurable excitement. Not however, until recent years has the drug found common favor among Caucasians for its stimulating effects to the intellectual powers. The English and Americans who, prior to the present generation, became devotees to opium were men of letters whose intelligence directed them to its use for the mental stimuli produced. The baneful effects of the opium habit were not pronounced until the process of chemical science gave us the active principle morphine, and resort was made to its use hypodermatically. So widespread is this abuse, especially among the cultured classes, that present conditions are truly alarming.

It was primarily a disease of luxury, for the drug is relatively expensive and, moreover, only those who have the intelligence to know its effects are likely to initiate its use. There are more than one hundred thousand known chronic users of morphine in this country, and of these no one class furnish so large a per cent. as physicians. The rate of increase among its votaries far exceeds our growth in population. Physical and mental degradation from cocaine abuse has developed so rapidly that even some of the large cities are striving to legislate it away from the public.

When chemistry was forced to give up this useful alkaloid for rightful use, intelligent men, many of whom were and are physicians, seized the opportunity, under guise of relief for human suffering, of placing all manner of erythroxylon preparations for promiscuous administrations by the public. The coal-tar preparations in their myriad combinations are habit-forming drugs, causing more baneful than beneficial results. Slaves to the chloral habit are not a few among persons whose vocations cause insomnia, yet whose intelligence and conscientious convictions restrain them from using or administering any extract from the poppy. Another class, esteeming themselves still more conservative, seek the seductive influence of chloroform or ether to ease their neuritic pain and soothe their mental unrest. I name but a few of the common habit-forming drugs, regarding it as presumption on the intelligence of those who compose this Society for me to do more than direct your attention anew to the prevalence and growth of the drug habit and solicit your intelligent cooperation to a rational solution of its cause and restriction.

It is not only true that physicians, more than any other class, are the slaves to narcotics, but it is a fact that those who do nearly all their work in a country practice furnish the larger per centage of morphine users. Modern civilization either produces more and greater aches and pains, or else the present generation is less tolerant. The present requirements of business and social conditions increase the demand and lessen the resisting power against narcotics. An imperfect nervous system, craving stimulation or narcotization, is no less a physical defect that the imperfect eye, yet what person would tolerate for a day even a treatment to the eye, the ultimate results of which he well knows are injurious. The query then is, Why do persons of equal or greater intelligence permit the use of stimulation or sedation to the nervous system, well aware that mental obliquity is added to physical derangement by the continuance of such drugs?

Immediate relief for acute suffering and temporary benefit in chronic painful conditions is a strong argument by the patient, but unless possessed of the intelligence directing him how and what to use for relief, he will not initiate its use. Once instructed in the successful application of a remedy, without the additional information that relief came by the use of a habit-forming drug, invites its repetition. Responsibility is traceable,

[1] Read before the Nebraska State Medical Society.

then, to the intelligence placing the remedy at the disposal of all who apply, if the user has not had equal instruction as to its baneful effects.

The cough syrups and lozenges, catarrh powders and kola drinks when not supplied to *all* by the druggist and soda-fountain vendor can be had at the grocer's, with printed instructions extoling their virtues. Progress in the science and art of compounding drugs enables pharmaceutical houses to exhibit myriads of preparaionts, many of which are very harmful to use. These concerns, founded for purely business ends, use numerous avenues of introduction for the consumption of their products. They are represented by shrewd managers who know well the advantages gained by endorsement from medical men. The general public cannot exercise intelligent discrimination, but, trusting to the "written testimonial of the doctors," they subsequently discover the deception. In this country the ease with which the title "doctor" is acquired and its indiscriminate application greatly lessen the ennobling and beneficial influences rightfully belonging to the thousands of able medical men past and present, whose knowledge, wisdom and integrity, concerning the physical and mental welfare of the human race, surpass every other profession. A more liberal education of the people is a commendable suggestion, but it will serve only as a little greater safeguard against dishonesty among the better educated in science and art. We take high place as one of the learned professions, yet within our ranks is found the largest proportion of chronic drug-users. They are among us, but not of us.

The best evidence possible confirming the high value of our currency is seen in the frequent attempts at counterfeiting. The multiplied pathies, like parasites, are but an excrescence on the great body of honest workers in our profession. It sometimes happens that a person possessing the mental, educational and legal requirements for practising the healing art, becomes infected with parasites of popularity and commerce which completely mask all conscientious appreciation of the patient's subsequent condition. The exceptions verify the rule and we must look for relief to the great body of men within our ranks, whose integrity of character cannot under any circumstances be purchased.

Education is demanded, but character is imperative. Wholesome legislation is good but those in our ranks who rise to the privilege of our opportunities in not only relieving but preventing disease are the men who ennoble our profession, and are infinitely superior as public benefactors to the legislators who enact or the chief executive who endorses class legislation. The intellect may see an evil and its remedy, but without the man of character in control such knowledge is harmful.

Not a few physicians, zealous to accomplish cures, overmedicate, and, finding other patients surfeited by the drug habit withhold the exercise of equal therapeutic measures for their liberation. It sometimes happens, too, that the busy practitioner, wishing to expedite the interview with some undesirable patient, suggests an efficient remedy, but puts no restriction on its continued use. This is more frequent in chronic neuritic patients, not so ill but that they can go about their work and make periodical visits to see the doctor. We are all familiar with chronic drug-users who trace their slavery directly to the advice of some doctor, who we well know is a competent and thoroughly conscientious physician, yet in an unguarded moment gave unwise counsel. I am not, however, unmindful of the fact that such accusations are many times more numerous than the truth warrants; what everybody says is usually not true.

In Colorado the medical profession has shown what a united and continuous effort in politics can do; and I feel sure we will not neglect our privilege in using the ballot advisably in Nebraska should our future suffrage be sought by an aspiring executive who delights in ignoring requests from the best thought in our profession. Wholesome legislation is desirable for the protection of the innocent, but we cannot legislate into man the character that impels him, with or without law, to right actions toward himself or his fellow men. The *man* in medicine, as in every vocation in life, is controlled by motives higher than civil law. Medicine is an exacting and jealous mistress. The public demands much of us for scant reward. If we would rise to the opportunities of our profession for relief of human suffering, we must daily live the life, exhort the precept, and practise the truth, which we as medical men know concerning drugs and their use, for liberating, rather than enslaving human beings.

TWO FATAL CASES IN INFANTS—PEMPHIGUS AND ERYSIPELAS.[1]

BY FRANK S. MEARA, PH.D., M.D.,
OF NEW YORK.

IN the days of good Queen Anne who was herself possessed of no small medical interest, inasmuch as she was the mother of eighteen children and delighted the midwives of her time with regal perquisites, and whose bloated effigy in Westminster Abby bespeaks the strain that was put upon the royal kidneys, Addison wrote in the *Spectator* that the physicians of his time reminded him of Cæsar's description of the British Army, "Some of them slay from chariots and some on foot," and further, "We may lay it down as a maxim that when a nation abounds in physicians it grows thin of people"; and so I fear if Addison were present to-night to hear the title of my paper, he would exclaim with another outburst of classicism, "tempora mutantur, sed medici nunquam."

But long before this caustic wit had launched his shafts of ridicule against our noble body, a

[1] Read before the Quiz Medical Society.

man of far keener perspicuity and higher literary attainment, not without humor, had written in the "Canterbury Tales" these lines:

"And when that Nature will not werke
"Farewell Phisick; go bear the man to kircke,"

and with this kindly explanation of our results, from the father of English verse, I beg your indulgence in the citation of these two cases.

On August 16, 1898, I was called to see a baby, seven months old, whose condition had on the morning of that day first given the parents cause for alarm. The history of the parents was negative; both of them were in excellent health. The only interesting fact about them was that the father was a butcher. There were two other children in the family—a little boy of five and a girl of three, both healthy. The year before both of these children had been under treatment by me for impetigo contagiosa, the disease being especially well developed in the little girl. This had been contracted in a house, a summer cottage, occupied during the preceding year by a Portuguese family, whose children had been afflicted in common with many school children by a skin eruption, known in local parlance as the "Portuguese itch."

The baby was a beautifully healthy specimen of infancy, still on the breast, and had never been ill. For four or five days the child had been ailing, but no history of any significance could be obtained, except that the day before the mother had eaten liberally of lobsters and then partaken of ice-cream, from which delectable ménu she had suffered no bad effects. The child had grown suddenly worse that night and its peculiar appearance had aroused the parents in the early morning to the advisability of medical attendance. The parents were intelligent, but had never had any experience with sickness in children.

On my arrival the appearance of the child was alarming. The baby was stuporous, the eyes fixed and staring, the face livid, the lips cyanotic, the skin cold, the muscles of the hands and mouth twitching. From the feeling of the skin one would never suspect fever and yet the temperature taken at once in the axilla registered 105° F. An examination of the chest revealed a few râles in the right lung.

A certain amount of fever, bacteriologists tell us, is probably a favorable reaction, diminishing the virulence of the toxins that may be circulating in the blood, and 105° F. is not excessive in a child; but to me at that moment it seemed that the vital centers were being overwhelmed and that the fever *per se* was in part responsible for it. At any rate, after a hypodermic of digitalin, gr. $^1/_{1000}$, and a few drops of whisky by the mouth, I put the child into a cold pack until its temperature was 101° F. During the application of the pack I made an abortive attempt to wash out its stomach and gave large saline enemas with but little result, so far as a movement was concerned. This was at 10 A.M. The child on removal from the pack improved at once, a glow coming to the skin, the twitching disappearing, the pulse improving, and it soon sank into a quiet sleep. At 3 P.M., five hours later, the temperature had gone up to 104° F., the lips were again cyanotic and the baby was crying loudly, apparently from pain. Numerous râles were heard in both lungs, due to edema from failing circulation. Again the pack was given with stimulants until the temperature was 100° F. and again the condition markedly improved only to be followed by a gradual rise.

While giving the pack I noticed a vesiculopustular eruption the size of a dime on the left buttock that looked like a patch of impetigo and which at that time was considered to be such. That patch was the beginning of one of the most interesting features of the case.

The next day, inasmuch as the condition of the child seemed dependent on the temperature, I ordered the nurse to give a pack whenever the thermometer registered 104° F. or above. This

day it received but one and with the same satisfactory result.

I will not go over daily details of the treatment, but will say in brief that during the child's illness of thirteen days it received twenty-one packs or sponges, at the intervals and with the results shown by the temperature chart.

The bowels were obstinately constipated and responded only after a liberal administration of calomel and castor oil and the use of suppositories. Fearing the possibility of some disorder of the mother's milk, I put the child on a modified milk mixture of fats, 3½; carbohydrates, 5; proteids, 1¾.

On August 20th the eruption began to force itself on my attention. It had spread from the initial focus over a great part of the buttock. It now showed an intensely reddened area, a little bluish in the center, from which the epidermis peeled off as in a sunburn; there was no thicken-

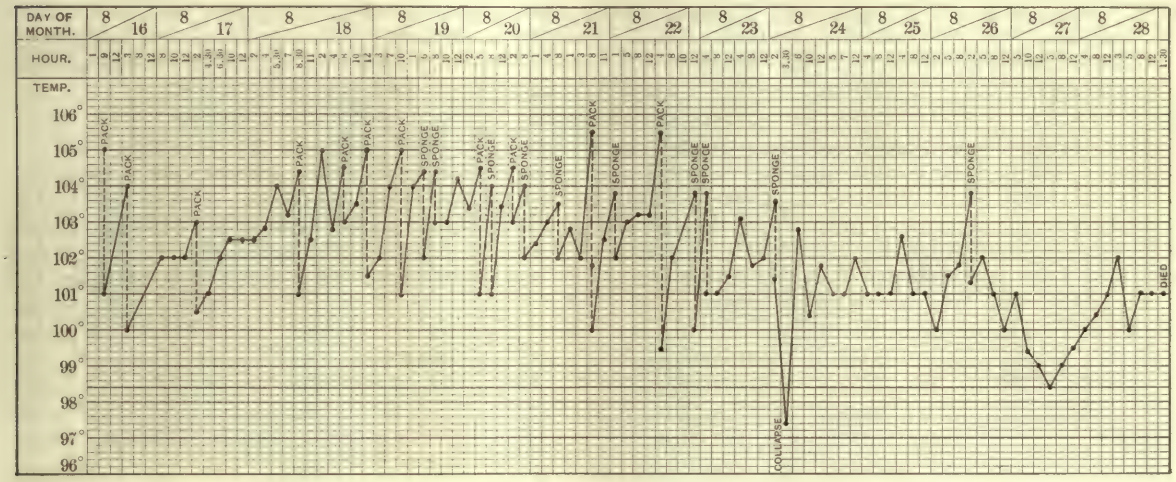
ing of the dermis, no ulceration and no pustulation.

The next morning, the 21st, the temperature rose to 105.4° F. and râles appeared in the chest. On the 22d the eruption appeared on the other buttock and on the vulva, commencing in each place as an isolated spot. Spots apeared on the nose on one ear and on a toe; later spots appeared on an arm, the face, thighs, lumbar region and back of the neck. On the trunk and thighs the spots spread over considerable areas, the epidermis peeling off in great flakes; no true vesicles were seen here, because, I suppose, of the maceration caused by the frequent packs. On the face, arm, and toe the spots were limited, the size of small coins, papular at first, then vesicular, and desiccated under the application of drying powders. The photographs give you some idea of its distribution. The light and shadow effects convey the impression of ulceration, which nowhere occurred.

head. It continually uttered a whine that at times became a sharp cry. It seemed indifferent to handling, but took its food well. The nurse reports six or seven slight convulsions.

The next day the cerebral symptoms abated, though retraction and rigidity persisted. The lungs were clear; the bowels under control. On the 26th there were convulsive movements; the lungs clear, but the breathing feeble.

On the 27th the morning temperature was normal; the stools were horribly offensive and light clay colored; the child evinced some abdominal pain. There was no strabismus nor convulsions, but the left pupil was dilated much more than the right and the left side of the face drooped. The tongue and lips were dry. There were violent coughing spells at times and the nurse reported that she wiped a few flecks of blood from its mouth. On the 28th it suffered a sudden collapse in the morning, but revived on stimulants. The cerebral symptoms were less



Case 1.

On the 22d there began a restless twitching of the head, opening and shutting of the mouth and occasional internal strabismus, the first signs of meningeal involvement. The evening temperature was about 105.6° F. and râles were heard in both chests. On the 23d the stools suddenly became very numerous, but of good color. The nurse reported that about noon the child seemed to go into collapse, but revived on stimulation with whisky. It had several paroxysms of hard coughing, but the lungs were clear and no cerebral symptoms were manifest.

The next morning, at 2 A.M., it had another sinking spell; cerebral symptoms now became marked; the head was drawn back; the muscles of the neck were tense; at times internal strabismus occurred, again internal strabismus on one side and external on the other, or, more properly speaking, conjugate deviation. The arms were rigid at the shoulder, the hands simulating the *"main en griffe,"* thumbs flexed into the palms, elbows flexed and hands raised toward the marked. The next morning at 4:30 the child died.

I was fortunate in obtaining an autopsy on this child, but was not allowed to remove the brain or cord. The baby was still in good flesh, as the photographs show. The heart was normal. The lungs showed areas of congestion along the posterior borders. The stomach was negative, but the small intestine showed patches of congestion, three or four in number and widely separated. The mesenteric vessels near the patches were deeply congested. In the caput coli and the two or three inches of the large intestine adjacent to it there was an area of marked congestion in which were sharply circumscribed petechia or extravasations, varying in size from that of a pin-head to that of a pea. Two or three more such patches occurred at intervals along the large intestine. The liver, spleen and kidneys were negative on gross examination.

Dr. Vanderpoel Adriance kindly examined sections from the lungs and reported scattered

patches of consolidation of the type of bronchopneumonia. As I was far removed from any medical center it was impossible for me to obtain cultures from the lesions and blood before death or from the tissues after death.

The diagnosis, then, was acute pemphigus, acute enterocolitis, bronchopneumonia and acute cerebral meningitis.

A review of one's own cases is a wholesome, but often a mortifying procedure, for it emphasizes our sins of omission as well as commission. I never feel how inadequately I have observed my cases until I review my notes, nor how inadequately I have noted my observations until my attention has been called to the fact by some one else. For example, I read an article the other day in the *American Journal of Medical Sciences* by Da Costa, on "Erythematous and Measly Rashes in Typhoid Fever" that recalled a case I had last summer of an erythema in a typhoid case. I remember, too, of remarking to the nurse that one might think our patient had scarlet fever, and yet on referring to my notes on the case I find it had nowhere been recorded.

Before throwing this case open to discussion by those wise in matters dermatological, I wish to say in defense of my diagnosis that I am aware that the term pemphigus has been loosely used to designate any condition accompanied by bullæ, but that I think this case may be considered as belonging to the more restricted class in which, as Hyde puts it, "the bullæ are either the main feature or one of the main features of the disease." Morover, it seems to me that this is one of that rarer variety, called acute pemphigus.

Payne, who treats of pemphigus in Allbutt's "System," mentions the fact that in nearly all the cases of acute pemphigus that he has collected in which there has been no history of a wound, the patients have been butchers or in some way connected with animals. It is an interesting coincidence that my case should have come under the same category. He believes that there is a specific inoculable disease after the type of pemphigus. In five cases cited by four different observers a diplococcus, which has been named the diplococcus of Demme, was isolated from the bullæ and appeared to be specific. He says the disease has the appearance of a septicemia, beginning with chills and a rigor and a rise of temperature. The eruption begins on one part of the body, but spreads rapidly and may cover nearly the whole surface. As the eruption spreads the general symptoms are aggravated. Cerebral excitement and delirium are often present, and may give place to profound coma. The temperature may rise above 104° F. The attack is often fatal in from one to five weeks.

In the *Deutscher Archiv für klinische Medicin*, March 23, 1899, Köhler cites a case of acute pemphigus in a child of six months, which was characterized by a sudden onset with high fever and the appearance of blisters over the body on the following morning, some of them as large as a quarter. On the following day new crops of blisters appeared from the contents of which were obtained the *staphylococcus pyogenes aureus* and a diplococcus resembling the organism of Niesser (Demme?). The child died with the signs of a severe bronchitis. Two sisters, who had care of the child, were attacked, and four more cases developed among those intimately associated with the family. He speaks of the cases as being characterized by the appearance of blebs on a perfectly sound skin, healing in one part and appearing in another. This was a feature in my own case which I fear I have not sufficiently emphasized. These new eruptions were associated with exacerbations and remissions of fever. The disease lasted from two to four weeks, having the course of an acute exanthem.

Dr. L. Emmett Holt reports in the *New York Medical Journal*, February 3, 1898, a case of acute pemphigus neonatorum proving fatal in a few days, in the vesicles of which was found the *staphylococcus pyogenes aureus*. All the deep organs were intensely congested and some hemorrhagic Peyer's patches and solitary follicles of the colon were found. I wish you to compare the picture given in his article with my photographs; also to recall the condition of the intestinal tract in my case.

Hadley and Bullock of the London Hospital cite a case of a butcher, twenty-three years of age, who sustained a wound in the hand while dressing a sheep. This wound suppurated and three or four days later bullæ appeared on the face, trunk and extremities. Vomiting and severe diarrhea intervened; a septic temperature ensued and death followed in thirteen days. The mesenteric glands were enlarged and the solitary follicles of a greater part of the large intestine and the follicles of the small intestine for about three feet above the ileocecal valve were enlarged and congested. A diplococcus, differing from any well-known pathogenic coccus, was obtained from the vesicles.

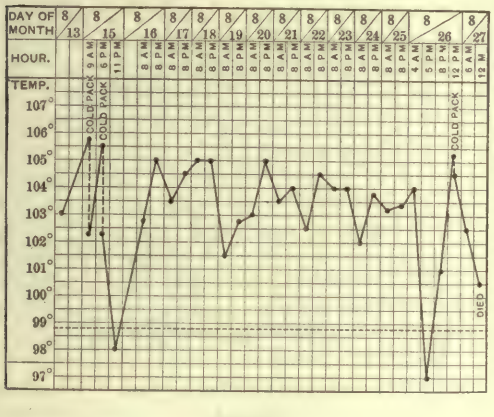
Before considering the probable character and mode of infection in this case, I will invite your attention to the second case, that of erysipelas.

August 13, 1899, I was called to see a baby of three months, previously perfectly healthy and of healthy parentage. The child was on the breast and splendidly nourished. The mother reported that during the preceding twenty-four hours it had been ailing and that that morning it had vomited and shown some twitching of the limbs. The examination was negative. Temperature was 103° F. in the rectum. Deeming it to be but some slight gastro-enteric disturbance so common among infants during the hot season, I ordered it a cathartic and small doses of aconite. The next day it appeared so much better that the parents did not consider it necessary to call me, but on the following morning it was seen to be worse. When I saw the child it was very feverish, the thermometer registering 105.8° F. The stools were green. I washed out the stomach, obtaining only a little mucus

and some curds of milk. The colon was irrigated and two stools better in character followed. These procedures were followed by a cold pack, until the temperature was 102.5° F. The child seemed much more comfortable and quiet after the pack. Castor oil was then ordered to clear out the upper bowel. At 6 P.M. the temperature was again 105.5° F. and again a pack was given until the temperature was below 102.5° F. A little red spot had appeared on the cheek, under the left eye, that looked like a mosquito-bite and did not impress me as being of much consequence, but the next day, the 16th, this little spot had become a brawny, red swelling, and had spread over the bridge of the nose and under the right eye. The evening temperature went up to 105° F.

Feeling satisfied of the true character of the trouble, I ordered an application of a 50 per cent. ichthyol ointment to the inflamed area and for the bowels an intestinal antiseptic (bichloride and salol), as the stools were still unsatisfactory.

The next day the inflammation spread some-



Case 2.

what, but on the whole the child was more comfortable. I ordered the child taken from the breast, the breasts pumped and the child fed with this milk and barley-water, fearing lest the mother might become infected, as she herself had had erysipelas when a child, and I believe it is generally stated that those who have once had erysipelas are rendered more susceptible to it after a brief period of immunity. The next day more of the right cheek was involved, and the skin of the neck invaded. The face now had the typical appearance of a severe erysipelas.

At this time, on the advice of Dr. Alfred Hand, I tried the time-honored treatment of iron. On the 19th the area of inflammation seemed softer and the edge fading. I should add here that the lungs had remained clear and the heart of good force. Moreover, the child was taking its food well.

On the 21st the face was much improved, but a diffuse blush extended down the trunk and arms. This was discouraging, for it showed that I had to do with an erysipelas migrans which is prone to last for some time and in so young an infant must eventually exhaust. W. Watson Cheyne says that erysipelas in infants tends to assume this wandering form.

The next day the face showed still more improvement and the redness was fading from the upper part of the chest and back, but the lower part of the back and arms were now invaded; this was not brawny as on the face.

On the 23d the erythema had spread over the buttocks, while the upper two-thirds of the trunk had become quite clear. Both arms were now involved in their entire extent, the upper clearing as the forearms were invaded.

Perhaps it would be well here to interrupt the description of the course of events to say a word about the character of the inflammation. It was not as severe on the trunk and limbs as on the face. In the former sites there was deep redness, but not much thickening nor edema. The advancing edge was always sharply defined. The redness disappeared momentarily under the pressure of the finger. On the face the inflammation was brawny and edematous, the swelling causing an obliteration of the features and complete closure of the eyes for a considerable time. The swelling involved the ears, the lower half of the forehead, both cheeks, the bridge of the nose, the upper lip and the chin but slightly. This curious exception of a general spread is noted by nearly all writers.

On the 24th the redness had nearly disappeared from the trunk, but had spread down the thighs and from the forearms to the hands.

On the 25th the inflammation had entirely disappeared from the face and trunk and almost entirely from the buttocks; it had quite gone, too, from the thighs and upper arms. Both forearms and hands were now severely inflamed, being swollen and brawny; the hands were puffed, like balls, and very tense. In spite of all this infection the child was still taking its food well, but the iron made it retch and it had to be discontinued.

The next day the inflammation was less on the arms and hands, but had now spread down the legs to the ankles. On this day, too, appeared a slight redness on the right shoulder and chest and patches of erythema appeared on the face and chest, but disappeared again in a short time. The vulva became swollen and edematous. This curious feature of the implication of the same part of the body a second time I find mentioned by Cheyne.

On the 27th the arms, legs, and vulva were better; the hands still swollen. The only parts of the entire body that had not been affected were the feet and scalp. The stools were now foul and frothy. The next morning the child died, thirteen days after the appearance of the skin lesion.

The treatment was the consistent use of ichthyol and the tincture of the chloride of iron, together with care of the bowels, baths for pyrexia and stimulation when needed. It was simply marvel-

ous to me how well the child stood this long siege and the involvement of an area of skin, which if burned to the second degree would have meant death in a short time.

As regards the treatment aimed at the condition itself, once could find justification for his procedures if he were to prescribe with his mental eyes shut, if he were content to take any of the drugs advised, for few conditions outside of diabetes and neuralgia have nurtured a more prolific formulary.

My own procedure was based on that in vogue at the time at the New York Hospital, namely, ichthyol which as a local antiseptic seemed rational, and, a deference to a time-honored empirical procedure, the administration of the tincture of the chloride of iron.

One feels a little timid about pointing the finger of scorn at empiricism, even in these days of therapeutic nihilism, when one is forced to recognize the value of such drugs as iodine, mercury, and arsenic, in the face of a lamentable paucity of facts concerning their *modus operandi.*

Warren of Boston in Dennis' Surgery recommends the use of ichthyol when strong antiseptics are not to be used and such was the case in hand.

Of local treatment, Osler says that ichthyol is at present much used, but perhaps as good an application as any is cold water, which was highly recommended by Hippocrates.

Watson Cheyne advises tepid sponging or cold baths for the hyperpyrexia. He endeavors to give new life to the failing custom of painting the advancing margin with iodine or silver nitrate, explaining that it increases the leucocytes and wards off the spread of the condition. In mild types this accumulation of leucocytes, he says, is characteristic, while ordinarily they offer no efficient barrier. Ziegler puts it nicely when he says, "they seem rather to limp after it."

A suggestion made by Fischer of St. Petersburg, quoted in the *Philadelphia Medical Journal* October 14, 1899, to use compresses of 85- to 95-per-cent. alcohol, in view of the reports of its efficacy in the inflammations caused by carbolic acid and its well-known antiseptic power, may have something in it. I simply mention this as among the newer methods outside the standard text-books.

As for systemic treatment, the use of the tincture of the chloride of iron is mentioned by all authorities and it is extremely interesting to observe the unanimity in their attitude toward it. They observe that which the newspapers of the day have made familiar to us, "a strict neutrality" —no enthusiasm, no condemnation.

There remains one other treatment that appeals to me strongly. In the *Lancet,* February 19, 1898, Magier reports a case of erysipelas, relapsing and developing a grave endocarditis, which was treated with antistreptococcus serum with immediate and satisfactory improvement, resulting in early recovery.

In the *Lancet,* June 24, 1899, Bond reports two cases of facial erysipelas treated successfully with antistreptococcus serum. If the streptococcus is responsible for this condition it certainly seems rational.

Now, is the ubiquitous *streptococcus pyogenes* responsible for erysipelas under the alias of *streptococcus erysipelatus?* It would be hard to determine from the literature.

Bacteriologists say "yea" and "nay." Authorities are always dogmatic, right or wrong. The clinicians in the meantime hesitate. Tyson in his new Practice emphasizes the similarity between the two germs without committing himself. W. Watson Cheyne, who writes the article on erysipelas in Allbutt's System, in discussing the two germs, leans toward the specificity of the *streptococcus erysipelatus.* He thinks the suppurative complications elsewhere are due to a mixed infection. Ziegler does not commit himself as to their identity. Osler speaks of the complications as being due to metastasis, that is, caused by the same germ. He also calls attention to its relation to the ordinary pus germ by the frequency of the small cutaneous abscesses in the face, forehead and scalp.

Regarding the mode of infection, while many writers insist that there is always a break in the continuity of the skin and mucous membrane at or near the site of the initial lesion that affords an antrum for infection, Strümpell says it cannot be denied that there are cases of facial erysipelas in which it is absolutely impossible to make out any cutaneous excoriation and (I emphasize the following) in which there is an initial stage with feverish symptoms preceding the localized trouble in the skin. Such cases suggest the thought that erysipelas is like the acute eruptive diseases and that it is at least possible that infection may take place in some other way than the one mentioned.

So much for the individual cases. I now wish to occupy a moment or two of your time in propounding a few questions which I hope will provoke a fruitful discussion.

What were the germs concerned in producing these two well-recognized pathological entities?

The past few years, and especially that period which for most of us measures our interest in medical matters, may be said to have witnessed the apotheosis of the micro-organism. Every clinical type of disease, that is, every complex of symptoms sufficiently well defined to be recognized as individual, and many more whose variations defie strict differentiation, have been dignified with names and titles, the possession of which, like property, being nine points of the law, they retain with wonderful pertinacity Each disease, so defined, was considered as worthy of its own germ and specificity ran riot as a natural result.

The reaction is already occurring and in a little while we shall in all probability be lending our earnest attention to the iconoclasts.

Those of you who have read or will read Hueppe's little book will appreciate what I mean. It is a plea against specificity in disease and

though extremely radical to those of us who are just feeling ourselves firm in these new beliefs, still is full of valuable suggestions and undoubtedly contains many just criticisms.

Is there a specific germ of erysipelas? Is there a specific germ of pemphigus? You have heard the evidence as quoted in this paper. If there are specific germs in these cases, where did they come from? No case of pemphigus had been known in that locality in the experiences of a practitioner whose professional work in those parts covers thirty-three years. The parents had never seen or heard of a similar case. If it is due to some germ associated with animals, then, of course, the father might have been the source of infection; if not, this specific germ must have led a saprophytic life for countless generations and then at its first introduction into the human body caused this highly virulent intoxication. Is it not strange it should have so rarely found a suitable host?

And the erysipelas? No case had occurred to my knowledge in the town in the past four years; none in that house at any time. What kind of an existence does it lead between its attacks upon the human body?

Now as for the latter, there is sufficient evidence to make it probable that it is identical with the *streptococcus pyogenes,* causing a manifestation under certain conditions of growth and resistance of the tissues which we know as erysipelas. The change in the virulence and morphology of germs under varying conditions of nutrition and environment is too familiar to detail.

The *staphylococcus pyogenes aureus* has again and again been obtained from the vesicles of pemphigus and that, too, in the absence of other germs of etiological significance.

May we not, then, look on these two conditions as due to the same germ or, at least, as due to one of the common pyogenic organisms, producing these apparently varied diseases, simply because of modified metabolism during their saprophytic existence?

Let us take an affirmative answer to this question as a working hypothesis. What was the mode of entrance and what determined the toxicity and nature of lesion provoked? In the case of the erysipelas, it may have been a minute abrasion in the neighborhood of the initial focus. In the pemphigus it may have been by a similar antrum or by way of or, indeed, originating from a patch of impetigo.

One other way has suggested itself to me. Could it have been from the alimentary canal? It has seemed to me that the gastro-intestinal tract has been in some manner responsible for these conditions. Gastro-intestinal disturbance was present in both; in one the autopsy showed a marked enterocolitis. Both began with symptoms of severe toxemia; forty-eight hours before the local lesion was seen at all in the erysipelas and equally long before the local manifestation was of sufficient importance to attract attention in the pemphigus. In both, in other words, the period was like an invasion of an acute exanthem.

Such symptoms as these children displayed in the early hours of their illness I have seen again and again in simple functional derangements of the bowels, which have been speedily terminated by a brisk purge, but in one case, five years ago, ending in death in twenty-four hours. This last case presented the picture of profound poisoning.

I believe the part taken by the bowel in all these cases was to furnish a toxic material that reduced the resistance of the tissues to a degree that afforded a suitable medium for germs that under normal conditions they resist.

This great subject of auto-intoxication, too little appreciated even yet, can hardly be approached here even in the briefest manner, but as the key-note of my theory hinges on it in these cases, I will simply recall to you two broad generalizations. Auto-intoxication may occur from the normal products of digestion when the functional integrity of the epithelium of the alimentary canal is impaired, or, at least, we know that such bodies as albumoses, peptones and some of the crystalline bodies are toxic when injected into the blood and, second, that auto-intoxication may occur from abnormally digested or fermented foodstuffs, producing toxins and ptomains.

So much for the causes that lower the resistance of the tissues; now for the germ. We know that the common pus organisms can be found in the mouth of healthy individuals and be compatible with continued good health; we know, also, that they are rarely absent from the healthy intestine (Welch). Even the bacillus coli communis can take on pathogenic activities under suitable conditions, as its isolated presence in suppurative foci shows. Cheesman and Meltzer's experiments, published in the *Journal of Experimental Medicine,* 1898, show nicely how these germs can cause suppuration in tissues, when injured, that in normal states easily resist them, and how eagerly the staphylococci and streptococci take advantage of such opportunities is shown by their presence in such lesions as dysenteries and appendicitis.

Even as I write the *Lancet* is publishing the Goulstonian lectures, by P. Horton-Smith on the "Typhoid Bacillus and Typhoid Fever," in which is brought out most strongly the offensive alliance of these germs of the intestine and how the virulency of each in the presence of the other is increased, if once the barriers of defense on the part of the organism are let down.

Already this paper has become inordinately long. I hope you see the drift of my ideas—that most varied, common and uncommon manifestations of infection may arise in the body from identical or similar germs, always present, not to be sought after in mysterious places, seizing their opportunity when some slight slip occurs in the body's functions.

If this theory be in any measure true, how important become our efforts at prophylaxis and early consideration of the slight gastro-intestinal disturbances.

400 West End Avenue.

MEDICAL PROGRESS.

Obstruction of Bowels.—Intussusception occurs in almost half of the cases, and of these less than half form a tumor, writes H. C. DALTON (*St. Louis Med. Rev.*, Aug. 10, 1901). In these cases the bowels may continue to move, especially tending to looseness in the ileocecal or colic variety. Speaking broadly, intussusception occurs in early life, volvulus in middle life, gallstones in old age, while bands, adhesions, etc., occur at any age. In intussusception the pain, vomiting and tenesmus are almost constant symptoms, but they may vary greatly in degree. In volvulus a rapid ballooning of the abdomen rapidly follows the onset of pain, vomiting is often absent, the pulse weak and rapid, temperature subnormal. On account of the distention there is dyspnea. In bowel obstruction we must withhold all opiates or purgatives, for the former obscure diagnostic symptoms, and the latter, by adding to the bowel, peristalsis, aggravate the condition, induce vomiting and increase the shock. If hypnotics, warm applications, and high rectal injections do not relieve after a few hours, the wisest procedure is abdominal section.

Alcohol and the Neurons.—Observations along this line are important in that modifications of the central nervous system occasion alterations in respiration, circulation and temperature range. ARMAND KLEEFELD (*Jour. de Physiol. et Path. Générale,* July, 1901) has carried on two series of experimental observations. In the first he trephined the parietal region of a rabbit's skull under antiseptic precautions and without the use of morphine, ether or chloroform. He then closed the wound superficially and after leaving the animal for at rest two or three days injected into the jugular vein 100 c.c. of a 7-per-cent. aqueous alcoholic solution. After two or three minutes he raised a portion of the cerebral cortex. This was fixed in a mixture of potassium bichromate and osmic acid and submitted to the rapid manipulation of Golgi. In the second series he introduced 100 c.c. of a 15-per-cent. alcoholic solution into the stomach of rabbits and made similar examination of the cerebral tissue. Here the pathological changes were increased in amount over those found in the first series. As the result of his work he concludes that the modifications produced by alcohol are not to be considered as a form of degeneration of the nerve-cells, since the alterations appear in a very few minutes after the injection of the alcohol. The moniliform (beaded) state and disappearance of the piriform appendages are seen only in the finest protoplasmic prolongations and far removed from the cell-body. As the dose of alcohol is increased this condition augments and approaches the body of the cell. This appearance is characteristic and not like that produced by chloroform, morphine or chloral hydrate. Certain prolongations remain absolutely normal even after large alcoholic dosage. The axis-cylinder submits to alterations only after very large dosage (100 c.c. of a 25-per-cent. solution). The cell-body does not seem to be in any way changed. This is at variance with the views of Demoor and Stefanowska. These alterations are able to explain all the phenomena of inebriety.

Gastric Analysis.—From experiments on over a hundred dogs, with and without artificial gastritis, M. FRÉMONT (*Bull. Gén. de Thérapeutique,* July 30, 1901) finds that the total chlorine per liter of the gastric juice is practically constant, no matter how much the free or combined acid may be, or whether the acidity changes from cold, the emotions, or disease. This being the case it is of no value to estimate the total chlorine, and it should suffice to find the total acidity, and the organic acidity, the free HCl being the difference between these two. Commenting on this Mathieu claims that the amount of chlorine does vary and that a high figure following a test meal without preceding lavage, indicates a tardy hyperchlorhydria or slow motor activity. He states also that in asthenic gastritis with absence of free hydrochloric acid, the normal chlorine content is very much increased, while hyperchlorhydria without increase of chlorine, and especially with decrease of chlorine, indicate a grave lesion.

Mammary Lymphangitis and Galactophoritis.—Lymphangitis is commonly ushered in by a chill, writes C. H. MAYGRIER (*L'Obstétrique,* July 15, 1901), a rise of temperature, pain and diffuse redness over an area of the breast and enlargement of the axillary lymph-nodes. Galactophoritis presents induration of a mammary lobule, with fever, pain, and the issue of pus from the nipple on pressure. In 2,432 cases lymphangitis occurred usually from the third to the ninth day, and seldom after the twelfth day of the puerperium, while galactophoritis appeared between the sixth and twelfth day, never before the third day, but in a fair number of cases after the twelfth day. When the two occur together the lymphangitis generally precedes. Lymphangitis ends abruptly in one to three days, without abscess formation, and there is rarely a relapse; galactophoritis may be without chill, terminates insidiously, often relapses, and may, though rarely, go on to suppurative mastitis, so that the prognosis is more serious. Lymphangitis does not affect the child, while if the child continues to nurse a galactophoritic breast, it ingests the germs of pus. Prophylactic treatment should consist of careful cleansing of the breast and the hands of the mother or nurse before touching it; then before nursing the nipples and the child's mouth should be cleansed with boric solution. Cracked nipples may be treated with compresses soaked in 20 per cent. alcohol, or a saturated al-

coholic solution of orthoform. When galactophoritis supervenes, the mother should be isolated, the child kept from nursing, and the milk expressed, but if there is both lymphangitis and galactophoritis, expression may favor abscess-formation. Still, expression is the best treatment at our command, and carefully and gently done will meet with good results.

Leucocytosis of Rabies.—Very little investigation has hitherto been made in regard to this subject. The question as to whether there occurs in this disease a quantitative or qualitative modification in the number of leucocytes and, if so, whether it can be utilized for diagnostic purposes, both before and after death, has recently been studied by J. Courmont and C. Lesieur (*Jour. de Physiol et Path. Générale,* July, 1901). Their researches were carried on clinically on the man, cat and dog and experimentally on the guinea-pig, rabbit and dog. Their blood smears were stained with Ehrlich's tri-acid solution, eosine-hematoxylin, and thionine. They find that at times the total number of leucocytes is considerably raised, especially in the terminal stages. Often it is preceded by a hypoleucocytosis, particularly in rabbits. Independent of the degree of total hyperleucocytosis there occurs in man a marked increase in the number of the polynuclearneutrophilics so that they constitute from 84 to 88 per cent of the total number of leucocytes. This increase is established at the time of appearance of the nervous symptoms and augments until death. No abnormal leucocytes or nucleated red blood-cells are present. Good preparations can be made from the pulmonary blood within six hours after death, but this contains a less number of the leucocytes than other blood. They conclude that the total leucocyte-count is not available for diagnostic purposes at any stage of the disease. From the onset of the nervous symptoms the differential count is of great value. An increase in number does not absolutely establish a diagnosis as this is found in other conditions, but a normal or reduced number at this stage absolutely negatives a diagnosis of rabies.

Bacteriology of Influenza.—Although there is described a bacillus of influenza its etiological relation to this disease is not definitely settled. M. E. Sacquepee (*Arch. de Méd. Experimentale,* July, 1901) has investigated an epidemic of influenza from a bacteriological standpoint. During the course of this epidemic four micro-organisms were found predominant at different times. At the beginning this organism was a long bacillus which occurred extra-cellularly and was unidentified. The pneumococcus then became the chief organism found. Later a streptococcus was most abundant and, finally, the influenza bacillus of Pfeiffer was predominant. During all this time the clinical symptoms and the infectiousness of the malady remained the same, yet none of these organisms seemed to be essential to it. From these observations he is inclined to doubt that influenza recognizes a specific primary infectious cause.

Tubercle and Influenza Bacillus.—As phthisis and influenza are so frequently associated A. J. Comstock (*South. California Practitioner,* June, 1901) advises the use of Ziehl's stain for the tubercle bacillus and Loeffler's alkaline methylene blue as a counterstain for the influenza bacillus.

Zomotherapy.—The use of raw meat or its juice in tuberculosis is commented upon by I. Honig (*Klin. therap. Woch.,* July 28, 1901) as follows: In meat juice we possess a preparation which, owing to its ease of manufacture, price and efficacy, is to be preferred to factory products, though a specific action in tuberculosis has not been absolutely proven. It forms, however, a valuable adjuvant to the usual hygienic and dietetic measures.

Cause of Gastric Ulcer.—Some interesting animal experiments have been made by W. V. Yzeren (*Zeitschrift f. klin. Med.,* Vols. 43, Nos. 3 and 4) which throw considerable light upon the pathogeny of gastric ulcer. He found that rabbits in which the vagus nerve is cut below the diaphragm generally remain alive and healthy after the operation, but develop ulcers in the stomach which resemble those in man in that they show no tendency to heal, are generally single and situated in the pyloric region at or near the lesser curvature, and are preceded by necrosis of the mucous membrane. Both the mucous membrane and the musculature in the neighborhood of the ulcer generally remain normal. The cause of the ulcers in rabbits is to be found in a spasm of the pylorus caused by severance of the nerve, and it is more than probable that a similar spasm is the cause in man. That this actually occurs is proven by the fact that the contracted pylorus can sometimes be palpated and that intermittent retention of stomach-contents can be detected by the gastric tube. The actual cause of the spasm in man is less clear, but it may be due to an inherited or acquired irritability of the gastric ganglia, so that errors in diet will readily cause a contraction. In discussing the surgical treatment, the following measures are mentioned: Pyloroplasty, with 7 per cent. mortality and 55 per cent. failures; gastro-enterostomy, with 19-32 per cent. mortality and 20 per cent. failures; and, lastly, pylorectomy, with a mortality of 45 per cent. The least success is thus obtained with the simplest and safest operation. The author has achieved good results and few fatalities in animals by the extramucous splitting of the pylorus, and recommends a trial of this operation in man. It consists in incising the muscle of the entire portio pylorica longitudinally down to the submucous coat without any suturing.

Present Aspect of Antitoxin Treatment of Diphtheria.—The use of antitoxin has reduced the mortality of diphtheria from 65-25 per cent. to 16 per cent., but has proved still more efficient when the injection has been made during the first day. J. D. Steele (*Therapeutic Gazette,* July

15, 1901) states that the greatest benefit the antitoxin has conferred upon the laryngeal cases is the reduction of the number that require operation. Symptoms of heart-weakness, albuminuria and paralysis, are probably considerably more common, however, but this is not to be attributed to the antitoxin, but to the fact that so many more patients survive. As an immunizing agent also, the antitoxin has established its value.

A New Symptom of Pericarditis.—Having himself recovered from an exudative pericarditis, P. PREGOWSKI (*Münch. med. Woch.*, July 30, 1901) describes a peculiar subjective sensation which he has not seen recorded. Whenever he turned over in bed on his right side he had a strange feeling as if at the same time some mass in his chest were rolling from the left side toward the sternum. He thinks that a careful inquiry for this symptom may aid in the diagnosis of pericarditis.

Action of Berberin.—Owing to the warm recommendation which berberin has received in the treatment of the enlarged spleen of chronic malaria and leucemia, M. MOSSE and K. TAUTZ (*Zeitschrift f. klin. Med.*, Vol. 43, Nos. 3 and 4) have investigated its physiological action with the following results: Berberin influences bacteria in that it inhibits their growth and diminishes the products of proteid-decomposition; molds and yeasts are affected in a similar manner and the assimilation and growth of the higher plants are reduced. Toward animals, especially rabbits, mice, chickens and frogs, berberin acts as a strong poison which causes much malaise and emaciation, reduces the reflex irritability and locally damages the nerves. It is also capable of setting up an acute hemorrhagic nephritis and a leucocytosis, but the spleen is not affected in any way, neither macro- nor microscopically. In certain cases in frogs the spinal symptoms of strychnine-poisoning are prevented by preliminary berberin injections. An increase of that property of the blood which leads to decomposition of peroxide of hydrogen was absent, despite the leucocytosis.

Yohimbin as Aphrodisiac.—Some further favorable results of the use of yohimbin as an aphrodisiac are reported by A. LOEWY (*Therapie der Gegenwart*, July, 1901). He found that after castrating dogs, erections set in just as rapidly as with normal animals, so that its action is not dependent upon reflexes set up from the hyperemic testes. It is thus clear that the action of the drug will also be satisfactory in those cases in which impotence has resulted from disease of the testes.

Roentgen Rays in Sarcoma.—A case of recurrent melanosarcoma of the leg, in which amputation was out of the question, was subjected to extirpation by C. BECK (*Münch. med. Woch.*, Aug. 6, 1901) and the raw surface exposed to the Roentgen rays for from ten to forty-five minutes, with the gratifying result that no further recurrence became evident at the site and that several metastases in the neighborhood underwent complete cicatrization. The author considers the action specific and not identical with that of the ordinary cautery. He recommends a trial of this method in cancer of the breast after amputation to destroy all the cells beyond the reach of the knife.

Ligation of Mesenteric Vessels.—Injury to the root of the mesentery is always serious and, unless prompt surgical interference is instituted, generally fatal owing to the large vessels torn through. Even if these are ligated, however, gangrene of the gut is apt to follow. Concerning the latter point, D. WILMS (*Münch. med. Woch.*, Aug. 6, 1901) states from personal observation that ligation of the trunk of the superior mesenteric artery above and behind the pancreas is a dangerous procedure while ligation of the corresponding vein is generally not serious. The latter was found necessary in a case of deep penetrating wound of the abdomen in which perfect recovery followed.

THERAPEUTIC HINTS.

Cold Irrigations in Typhoid.—Recognizing the great value of cold baths in typhoid fever, LEMOINE (*Le Nord Méd.*, Aug. 1, 1901) replaces them where baths are impossible by rectal irrigations with boiled water cooled to 64°-68° F. These he repeats every three hours, or even every two hours in some cases. They are not so effective as the baths, but act more rapidly in cooling the patient, and in addition clean out the intestine. The author uses two liters (2 quarts) for each washing, and stops the current from time to time to allow the intestine to empty itself, lest too much pressure should increase the distention. If the water is too cold it may provoke painful contractions, and even facilitate perforation. By these irrigations the nervous phenomena disappear, delirium is the exception and the tongue remains moist, but the effects are more transient than from Brand's method.

Hysterical Arhythmic Chorea.—The four types of arhythmic chorea are that of Sydenham, chronic progressive chorea attacking the adult and continuous until fatal, the symptomatic choreas including hemichorea, congenital chorea, hemiathetosis and double athetosis, and hysterical chorea. This last is of extremely variable character, simulating the other kinds, and occurring at all ages. Its treatment has been very unsuccessful, but HUYGHE (*Le Nord Méd.*, Aug. 1, 1901) has been able to cure six cases by immobilization. The patient is chloroformed slightly, and the choreic limbs vigorously massaged, so that the patient feels it, and at times even painfully. Thus the choreic has the belief that she is being operated upon. The limbs are then placed in splints and immobilized for five or six days, and generally all choreiform movements cease. If they still persist, the limbs are again immobilized. This is a species of autosuggestion, which has met with some permanent successes.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

PARA-INFECTIOUS AFFECTIONS.

ONE of the most suggestive contributions to medical nomenclature in recent years is the use of the name of a disease as an adjective with the prefix *para* to denote that the symptoms or conditions described are only indirectly related to the disease in question. Fournier made the new term popular by his use of it with regard to the occurrence of sequelæ of syphilis, distant in time from the original attack of lues, yet unmistakably dependent on it for their etiology. The grouping of the parasyphilitic affections by a keen clinical observer has proved of great value in correcting our appreciation of the disease and its liability to produce hitherto unsuspected permanent effects upon the human system. The additional notion that these by-conditions of disease are probably due, not to the specific causative germ, but to toxins in the circulation was an accessory suggestion of far-reaching value.

We are familiar with similar by-conditions of certain other diseases that are of great interest. The now well-recognized special liability of children suffering from measles to contract diphtheria is probably an example of the toxin of the former disease preparing the soil in the human system for the luxuriant growth of the diphtheria bacillus. Diphtheritic paralysis is probably best classified as a paradiphtheritic action. Its occurrence is not separated, as in the case of parasyphylitic nervous ailments, by a long interval of time from the original attack of diphtheria, but it occurs at a time when the active diphtheritic symptoms are past and the best explanation of its etiology seems to be that it is due to the toxin of diphtheria still unneutralized in the circulation, or at least in certain susceptible parts of the system, after the cure of the original focus of the disease.

Recent investigations show that there are probably a series of paradiphtheritic affections that further observation will make easily recognizable as such. Walsh showed before the Philadelphia Pathological Society during the spring that the phagedenic ulcer of the cheek, known as noma, which occurs in the course of measles in run-down patients is almost surely a constant manifestation of the presence of the diphtheria bacillus and its toxins in the neighborhood of the lesion. This explanation of the etiology of noma had been suggested before, but the observed cases were few. The last investigator added eight new observations of noma in which the diphtheria bacillus was demonstrated. This sets all doubt at rest as to the nature of the lesion. Needless to say this confirmation of previous observations suggests a very hopeful therapeutic outlook for an affection that has been hitherto extremely obstinate to treatment.

This seems to be only an example of certain atypical and apparently unconnected complications that will prove to be associated with infectious diseases to which their relationship was unsuspected. Osler has pointed out that arthritis deformans very often follows severe infectious fevers and that there is apparently a special liability for it to occur after influenza. Stuart of Montreal showed that about one-third of the patients affected by this chronic deforming arthritis had a history of previous gonorrhea. It has been shown bacteriologically that the pus of osteomyelitic abscesses is often a pure culture of typhoid bacilli. Such cases of osteomyelitis occur as the result of injury to a bone some seven to ten years after recovery from typhoid fever. The typhoid bacilli seem to have been separated in the bone during the preceding attack of fever and to have acquired virulence for the individual once more after the period of immunity to the disease had passed. The trauma in such cases only furnishes

an opportunity for the walled-off bacilli to affect neighboring tissues by reduction of their resistive vitality.

In a word, there seems to be a number of affections, at present considered independent nosological entities, that are really manifestations of preceding infections. The recognition of the true identity of such symptom-complexes will prove an important step in advance in our knowledge of disease and will usually furnish valuable hints as to the therapeutics of these conditions. Possible connections of preceding infections with tissue changes that produce symptoms later are always to be borne in mind. It is probably that we have scarcely more than begun this interesting chapter of the para-infectious affections.

A GYNECOLOGICAL SCAPEGOAT.

FEW subjects have proved such a fertile field for the exercise of the pen and so profitable financially to the gynecologist and general practitioner as retrodeviations of the uterus. It has become almost axiomatic that in nothing can one so easily obtain the interest and coöperation of a patient as in anything connected with the sexual organs. The idea having taken root that a retrodeviation of the naturally movable uterus is a serious lesion, responsible for certain symptoms, nothing is more natural than that this condition discovered by examination should be made to bear the blame for many a pelvic pain.

The number of women who have been treated for the "misplaced womb" with no cessation of their pains and other symptoms, and are relieved by a course of catharsis, Christian Science, or other distraction from the genital sphere, shows the way in which the uterus has often been made the scapegoat, with complete disregard of constination, hysteria, and other common feminine disorders. That constipation can result mechanically from the pressure of so small a body as the retroflexed uterus seems almost incredible. The urinary symptoms referred to retrodeviation occur quite as frequently in its absence, as a result of inflammations of the urinary tract, urethral prolapse, cystocele, hysteria, etc.

Careful study of the subject cannot but lead to the conclusion that the symptoms attributed to retrodeviation of the uterus are due not to its altered anatomical position but to attendant complications. Neither can one fail to agree with Heinricius (*Archiv für Gynäkologie,* Band 63, Heft 3) that these complications are not caused by the retrodeviation. He holds that the pelvic circulatory stasis to which so much is attributed can result only from acute retroflexion which is rare. The endometritis and subsequent metritis which give rise to so many of the symptoms are often the result of infection, which is not favored by retrodeviation of the uterus. Further, such a displacement of the organ is often unaccompanied by endometritis. Pain in the back may be symptomatic of constipation, enteroptosis, disease of the vertebral column or cord, muscular strain, hysteria, neurasthenia, etc. How frequently are these conditions overlooked in favor of a protracted course of "local treatment!"

The frequency with which marked retrodeviation exists without giving symptoms, the relief of the symptoms which are often attributed to the uterine position by treatment of the complications alone, and the absence of any characteristic symptom or group of symptoms of uncomplicated retrodeviation of the uterus naturally lead to the conclusion that this has been made, often with purely honest motives, the excuse for a course of treatment which may have benefited the patient only after the manner of Christian Science. And after all it is hard not to agree with Mr. Dooley that "Christyan Scientists thinks there'se no such thing as disease, an' doctors think there ain't anything else. An' there-ye-are." Conservatism in at least the operative treatment of retrodeviation of the uterus is the logical conclusion.

SERUM INJECTIONS IN ANEMIC CONDITIONS.

ONE of the most interesting recent contributions to hematology is Hunter's theory of the septic etiology of pernicious anemia. As is now very generally known, he attributes the cause of this hitherto unexplained blood disturbance to an infectious focus somewhere in the system. Usually the infectious material is in the digestive tract and the absorption of toxic substances from it leads to the excessive hemolysis which is such a characteristic feature of pernicious anemia.

In Hunter's experience, the mouth, as a rule, has been the nidus in which infectious microorganisms have found a favorable location under eminently suitable circumstances of warmth, moisture and abundant food material. Carious teeth have seemed especially to be the foci of infection from which by deglutition constant reinoculation of the digestive tract has taken place.

Hunter's theory of the gastro-intestinal capillaries as the seat of abnormal hemolysis in es-

sential anemic conditions is not new. It is to be remembered that Sir Andrew Clark, always insisted on considering constipation as an important etiological factor in the production of the other obscure essential anemia—chlorosis. There is no doubt that the absorption of toxic substances from the contents of a sluggish intestine adds to the seriousness of chlorotic conditions. In these cases it has been considered, however, that the constipation is generally secondary to the blood changes. The lack of proper nutrition so diminishes muscle function that intestinal peristalsis suffers, as well as other muscular actions, in its proper performance. Whether bacterial toxins play an original rôle by causing abnormal hemolysis is at least doubtful. The primary condition in chlorosis seems to be a defective hemogenesis rather than any inordinate blood destruction.

According to Hunter's observations the streptococci have appeared to be the most prominent of the pyogenic micro-organisms in the production of serious blood disturbances. A very interesting and suggestive confirmation of this view of the streptococcic origin of pernicious anemia has come from recent observations in the therapeutics of the disease. In three cases, two of them under Hunter's own care and the third (the first recorded case, however) in other hands, the administration of injections of anti-streptococcus serum has been followed by rapid improvement. This amelioration of symptoms has continued until patients were restored to good health and, so far at least, the improvement has not been followed by the accustomed relapse. In one of the cases the interval of complete absence of symptoms has lasted for more than two years.

Of course these periods of recovery may prove to be only the well-known temporary ameliorations of the disease. Clinically, however, the improvement seems to be due to the use of anti-streptococcus serum. In two of the cases only the serum and certain intestinal antiseptics were administered. The effect of the serum may not be specific; that is, it may not act by directly neutralizing the toxins of streptococci present in the circulation, but only by tonic stimulation of the blood-making organs. More than ten years ago that acute clinician, Quincke, pointed out that even small injections of blood serum seem to bring about improvement in the blood condition of anemic patients, even those suffering from pernicious anemia. This same result has been noted by many observers in obstinate cases of chlorosis. The tendency to urticaria and erythematous eruptions, so common after injections of serum of any kind, shows how sensitive are the walls of the capillaries to action of certain well-differentiated principles that invariably exist in animal serum. Supposing this same effect to be produced on the capillaries of blood-making organs especially rich in their capillary network, the resultant stimulation can be easily understood.

There is no doubt that pernicious anemia is a much more common disease than it was thought to be only a few years ago. The serum method of treatment in hemic conditions is at least suggestive, and the recent reports of success with it should encourage its more extended employment until we are able to decide as to its actual usefulness.

From time to time the newspaper reporter outdoes himself in the effort to make copy. During the past week we have been amused by a number of items. We take pleasure in presenting a few to our readers.

The bacillus is the important item in the first brace; for instance, on the subject of old age, we have the following "made in France:" "Professor Gautier, a member of the Institut de France, has propounded a theory on the subject of perpetual youth. In isolating the bacteria of physical fatigue, he has found, he says, that it is a poison strongly resembling ptomain poison in nature. From this he argues that fatigue can, by the use of disinfectants, be avoided like any other poison, and consequently man need not weaken or age." This is a good enough tale for the *silly season,* which is the London title for this period of the year.

Another choice bit of tommy rot comes to us in a bacillary origin for epilepsy, as follows: "Prof. George H. French of the State Normal University of Carbonville, Ill., announces the discovery of a parasite which he says causes epilepsy. Cases were brought to the Professor's attention from all parts of the United States; he is rapidly developing his treatment, and when completed will give his discovery free to the world. He is known as the author of a work on zoölogy, and is a member of several foreign scientific societies." All hail to the new bacillus!

Mawkish sentimentality pervades a third in which it is reported that a certain Western physician is to give up everything, wife, children,

etc., etc., in order to devote himself to the cure of a case of leprosy.

Why it is that the laity go into hysterics at the mention of this very mildly contagious disease and the newspaper reporter uses up several inches in headlines is beyond the ken of sober-minded physicians who every day of their lives expose themselves to the contagion of diseases infinitely more dangerous than leprosy.

ECHOES AND NEWS.

NEW YORK.

Cremation of Garbage.—The cremation of the garbage of Queens Borough has proven to be a very satisfactory adventure. The crematories located in this borough are four in number and these are able to dispose of about 40,000 loads per year. Experience has shown that these can be operated at less expense than a reduction-plant and they are also much less offensive.

Mosquito Pest.—A systematic plan for the extermination of mosquitoes has been inaugurated by the residents on the north shore of Long Island from Rosyln to Huntington. The immediate work to be undertaken will be in charge of Mr. A. C. Weeks and Professor F. E. Lutz of the Chicago University, who will work in conjunction with Dr. C. B. Davenport of the Cold Spring Biological Institute.

The American Electro-Therapeutic Association.—This Association will hold its eleventh annual convention in Buffalo, on September 24th, 25th and 26th, 1901. Its headquarters will be at Hotel Niagara, and its place of meeting, at the Armory of the 74th Regiment.

PHILADEDPHIA.

Decrease in Hay-Fever.—The usual August outbreak of hay-fever has failed to manifest itself to any appreciable extent in the city thus far this year. The only apparent cause is the heavy rainfall during the month, rain having fallen on twenty of the first twenty-four days of the month. This is believed to have settled the dust and pollen sufficiently to keep in check the disease. If this cause acts until other conditions are more favorable a comparative immunity is looked for.

Appendicitis.—Philadelphia has lately been credited with being the banner city of appendicitis. Perhaps her blue bloods are addicted to the habit, but if the press reports are true the palm should go to Burlington, N. J., with its case of appendicitis in a goat which came to grief by the lodging of a rubber shoe heel in its appendix. Burlington holds the record.

Vital Statistics of Philadelphia.—Census returns show that Philadelphia with a death-rate of 21.2 per 1,000 for 1900 is exceeded by only four cities having a population over 100,000. The decrease from 1890 is also slightly under the average. A former port officer of the Bureau of Health states that the vital statistics of various cities are misleading and that the only intelligent method of making a comparison of the hygienic condition of our great cities is to take the reports of deaths from diseases alone and especially those diseases which are due to insanitary conditions or to ineffective efforts to prevent the spread of contagious diseases.

Smallpox Increasing.—Smallpox has slowly but steadily increased in the city during the summer months when it should be the most easily controlled. There are now eighteen cases in the city, almost entirely among white persons in contrast to the first of the year when colored people were affected. This year's record in Pennsylvania shows 946 cases and 7 deaths, while last year showed but 10 cases and no deaths.

Water Improvement Loan Completed.—The remainer of the loan for improving the water supply of the city, $9,000,000, was paid to the city by a syndicate August 22d. Work on the filtration plants has been temporarily crippled by the discovery of the omission of penalty clauses in the contracts.

Eye Disease from Public Baths.—Numerous cases of eye diseases are being treated at the hospitals as a result of bathing in the public bath-houses. The superintendent of baths points out that the fault is not in bad management but in the system itself. Although great care is taken to change the water in the pools, contamination by great numbers of bathers is inevitable. The remedy is the use of shower baths instead of pools. The public bath at 410 Gaskill Street is built upon this plan and is kept open the entire year. There is a nominal charge of five cents which is expected in time to pay all expenses. Each bather has a separate room, hot and cold water, clean towel and soap. The establishment is considered perfect from a sanitary standpoint.

CHICAGO.

Bacteria Found in Ice.—Bacteria, nitrates and ammonia in quantities forbidden by the laws have been found by City Chemist Bisbee in samples of ice of several companies dealing in the frozen product. Bacilli almost identical with those of typhoid fever were found in one sample, and other bacilli supposed to be characteristic of sewage were discovered in more than one block of ice. Ordinary city water, when exceedingly pure, has not more than one hundred bacilli to the cubic centimeter. Water called "usable" sometimes has as many as fifteen hundred per cubic centimeter, but the city water is never called usable if there are any sewage bacteria found in it. Freezing has a tendency to expel impurities from water, and therefore ice should contain fewer bacteria than the same amount of water. Twelve hun-

dred bacteria to the cubic centimeter are a great many.

Removal of Garbage.—The Nineteenth Ward Improvement Association was in earnest when it met a short time ago and denounced the present methods of leaving the streets uncleaned and the garbage boxes unemptied. The Health Department explains that the cause of the conditions complained of is an insufficiency of municipal funds. Whatever the cause may be, it is evident that difficulty exists. Any citizen may take the South Halsted car, alight near Twelfth Street, and see for himself the filthy streets and the overflowing garbage boxes that are the most salient features of the district. The city has never removed garbage as fast as it accumulated, and now bad has become worse. It is to be hoped that more attention will be given to this matter in the future.

The Tenement-House Question. — The Health Department has assigned territory to volunteer health inspectors, who are working in tenement districts. The specific cause of their appointment is that mothers need instruction in the care of their children. This instruction the volunteer inspectors will give, but they will concern themselves with the general conditions of tenement life and will be expected to make observations on such questions as drainage, ventilation, and crowding. While this work is noble and commendable, it is in its nature transitory and spasmodic. It is an outburst of individual philanthropy, creditable to those who participate in it, and gratifying to the city as a whole, but it makes still more apparent our lack of a permanent commission to which such duties naturally belong. The idea of a permanent tenement commission has been adopted in other cities with notable success. It is with the example of London and of Paris in their minds that the members of the committee of the City Homes Association makes the recommendation that Chicago "place upon a single responsible body the duties of regulating the existing tenements, of controlling the new buildings, and of rationally grouping the population of the city." This seems to be no chimerical scheme. It is in theory reasonable and in practice successful. That conditions in Chicago are so radically different from those of London and of Paris as to make impossible here what was perfectly feasible there seems unlikely. At the present time, both administration and reform are impeded by the way in which responsibility is divided between the Building Department, the State Factory Inspectors, the State Board of Health, the Bureau of Streets and Alleys, and other official bodies. The tenement house has become a question which cannot be treated incidentally. It needs special and detached attention. The New York Tenement Commission is now making plans for the organization of a municipal department which shall have powers even exceeding those of the Paris and London departments that have been mentioned. If Chicago means to concern itself seriously with the tenement house and, therefore, the health of its river ward population, it may have to adopt similar measures. At any rate, these measures deserve consideration.

Passavant Hospital.—Contracts have been let for an addition to the Passavant Memorial Hospital. This addition consists of a five-story stone and brick structure to cost $15,000.

GENERAL.

Northwestern University Medical School.—Dr. A. P. Ohlmacher has been appointed Professor of Pathology in the Northwestern University Medical School (Chicago Medical College). Dr. Ohlmacher has been connected with the Pathological Laboratory of the Ohio Hospital for Epileptics at Gallipolis, Ohio, and will for the time being continue the direction of that Laboratory.

Medical Congress in Egypt.—Invitations have been sent out for an international congress of medicine, to be held under the patronage of the Khedive of Egypt, at Cairo, in December, 1902. It will be the first great gathering of scientific men ever held in an Oriental country. The subjects to be considered more particularly, will be the diseases that come from the East, like cholera and the bubonic plague, as well as forms of liver complaint, dysentery and ophthalmia, prevalent in Eastern lands. Tuberculosis and the effects of climate will also be discussed. Among the medical men who are promoting the Congress are Abbate Pacha, Comanos Pacha, physician to the Khedive, Ibrahim Pacha Hassan, dean of the Cairo Medical School, Mol Eloui Bey, the ophthalmologist, and the chief Egyptian physicians, native and foreign. Dr. Voronoff is Secretary General of the committee in charge of arrangements.

Effect of X-Rays on Insects.—A recent test was made of the effect of X-rays on insects in the following manner: A box was made, half of wood and half of sheet lead. In the wooden half a number of larvæ of flies, bees, beetles, and other insects were placed, and the box was then put in the field of the X-rays. The insect colony at once became greatly excited, and after crawling to and fro, finally emigrated to the leaden half of the box, where the rays would not penetrate. The experiment was repeated many times and always with the same result. A similar experiment was tried with the blind larvæ of a certain species of beetle. A number of them were placed in an open cigar-box, which also contained a metal box with an opening. No sooner were the rays turned on than the insects showed signs of distress. Their uneasiness increased, and in a little while they all sought refuge in the metal box. As the larvæ in the second experiment were entirely sightless, their perception of the

rays must take place through the nerves of the skin.

Prize for Prof. van Gehuchten.—The annual prize of 5,000 francs for the best work in the province of medical research offered by the Belgian Government has been assigned this year to Prof. A. van Gehuchten for his works on the human brain and spinal cord.

Leprosy in Crete.—Dr. Ehlers, the Danish specialist, has been studying leprosy on the island of Crete, and estimates the number of cases at about 600. Prince George has lately directed that the lepers shall hereafter be isolated on the island Spinolonga, after the Hawaiian manner.

Seasickness Congress.—The following editorial note from the *Sun* is of interest: "There are certain maladies which, though not intrinsically funny, are for some occult reason treated almost universally as a very good joke, except by the sufferers. Seasickness, the most familiar of these, is at last to be rescued from contempt, for a congress is about to be held at Ostend, under the patronage of the King of the Belgians, for the purpose of inquiring into its nature and the best means of preventing and curing it. An elaborate exhibition has also been planned to consist of (1) specially constructed craft and apparatus designed to counteract the motion of ordinary vessels; (2) devices intended to check the temporary displacement of the viscera occasioned by such motion; (3) methods of supplying oxygen, ventilating, deodorizing and purifying the air below decks; (4) food, liquid and solid, for seasick patients; (5) drugs and other curative agents; (6) pamphlets and books dealing with the subject in all aspects. A series of experiments will be conducted by the congress on some of the boats that ply about Ostend and neighboring ports, and comparisons made between the several methods of treatment. Thus, one patient will be bound about the abdomen with flannel bandages, another will be provided with a pair of red spectacles, another will be dosed with cocaine, another will be placed in a cot on gimbals, and so forth through the several devices of disputed efficacy. No doubt many new methods of treatment will be proposed. The discovery of a cure is perhaps too much to expect, but we may reasonably hope that the congress, if it does nothing else, will at least do something toward giving seasickness its due. Other forms of shock are not treated as a joke, nor is this particular form either by those who are most familiar with it. The 'bad sailor,' the really bad one, takes it very seriously indeed, so seriously that it will probably be harder to find willing subjects for these experiments than for the experiments with the bacilli of bovine tuberculosis, malaria parasites and other such trifles. There is really no reason in the world, then, why this peculiarly unpleasant nervous disturbance should be laughed at. But public prejudice is so strong that it will never be treated seriously unless the members of the congress put it in a new light. Might they not be induced to attribute it to the mosquito?"

Oldest M.D. Graduate of Yale.—Dr. Chauncey Ayres celebrated last week his ninety-third birthday. Although he is feeble, the doctor is seen in the streets every fair day taking a walk. Dr. Ayres is the oldest living graduate of the Yale Medical School. He was in the class of 1831. Soon after his graduation he went to New York, and was one of the doctors in charge of the cholera hospital there during the epidemic.

New Lamp for Lupus.—A despatch from Copenhagen says that Dr. Sophus Bang, manager of the laboratory belonging to Prof. Finsen, inventor of the light cure for lupus, has constructed a special electric lamp, giving a feeble light, but which is extremely rich in chemical rays. The despatch adds that Dr. Bang used metal instead of carbon poles. The bacteria-killing power of this lamp is ten times as great as that of an ordinary arc lamp, and a lupus patient requiring seventy-five minutes' treatment with the arc lamp will require only from three to five minutes' treatment with the new one, which costs only $15.00.

Roentgen Ray Society.—The preliminary program of this Society offers the following papers:

Tuesday, September 10th, The Diagnostic Value of the Roentgen Rays with Special Reference to Their Application in Medico-Legal Cases, Mihran K. Kassabian, Philadelphia, Pa.; An Examining Frame and "One Minute" Localizer, with Demonstrations, S. H. Monell, New York; How the Induction Static Machine Can Be Excited Without a Separate Charter, John T. Pitkin, Buffalo, N. Y.; The X-Ray in Country Practice, Joseph C. Clark, Olean, N. Y.; What the X-Rays Show in Actinomycosis, G. E. Fosberg, Cedar Rapids, Ia.; X-Ray Work in Great Britain: Results of a Trip, G. P. Girdwood, Montreal, Canada; President's Address, Heber Robarts, St. Louis, Mo.; Researches in the Direction of Obtaining Shadowgraphs of the Muscles and Ligaments of the Body, H. Westbury, Harrison, N. J.; Brief Remarks on the Therapeutic Value of the X-Ray and Suggestion on a Universal Coöperation, Constantin V. S. Boettger, Ottawa, Canada; Some Medico-Legal X-Ray, Illustrated, F. Wesley Sells, Murray, Iowa: Investigation of X-Ray Problems, Virgilio Machado, Lisbon, Portugal; Skiagraphy of the Concretions in Urine, Especially Cystine, R. Jedicka, Chirurgical Clinic, Prague, Bohemia.

Wednesday, September 11th, Why Some Mistakes Are Made in Radiography, J. N. Scott, Kansas City, Mo.; Description of a Simple and Efficient Form of Electrolytic Interruptor, Elmer G. Starr, Buffalo, N. Y.; The Treatment of Cutaneous Cancer by the X-Rays, G. E. Peahler, Philadelphia, Pa.; Use of

the X-Ray as a Therapeutic Agent, Illustrated, H. P. Pratt, Chicago, Ill.; Some Light Rays in Tuberculosis, Dr. J. Mount Bleyer, New York; The X-Ray, an Absolute Necessity in Dental Surgery, Frank Austin Roy, New York; The X-Ray Tube, Emil H. Grubbe, Chicago, Ill.; Development in Crooke's Tubes in 1901, H. Westbury, Harrison, N. J.; X-Ray Machinery, W. C. Fuchs, Chicago, Ill.; The Relative Efficiency of X-Ray Generators, W. A. Price, Cleveland, O.; Position in Skiagraphy, M. E. Parberry, St. Louis, Mo.; Turck's Gyromele and the X-Ray in Diagnosis of the Diseases of the Stomach, Illustrated, J. Rudis-Jicinsky, Cedar Rapids, Ia.

Yellow-Fever Tests in Havana.—Newspaper comment is rife concerning the reports of experiments made in that city. Until Dr. Harvard, a careful and able observer, gives official sanction to these rumors it is unwise to offer any opinions concerning the value of Dr. Caldas' observations, especially since Dr. Harvard has already been reported as saying that the experiments are being carried out in a very loose and unscientific manner.

Obituary.—Dr. Alfred A. Dana of New York, while attempting to cross the Harlem Railroad tracks at Bronxville August 22d, was struck by a local express train and killed.

OBITUARY.

THOMAS MASTERS MARKOE, M.D.

New York has lost another of its illustrious surgeons. Ripe in years and well beloved, Dr. T. M. Markoe died last Tuesday, August 27th, at his summer home in East Hampton, L. I., at the age of eight-two years.

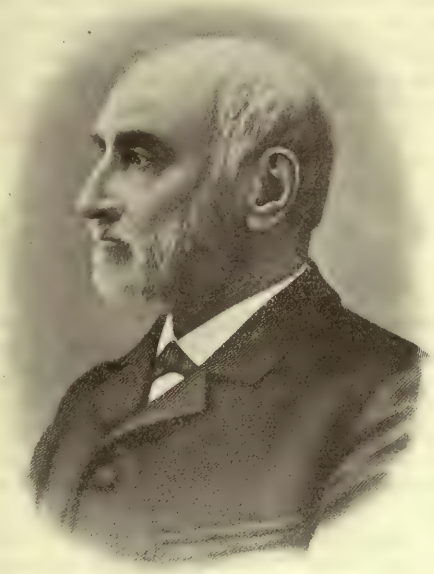
Dr. Markoe retired from active practice several years ago, by reason of advancing years. He was born in Philadelphia in September, 1819, and was graduated from Princeton in 1836, and from the College of Physicians and Surgeons in 1841. In 1839, while still a medical student, he became a junior assistant in the New York Hospital. He had been connected with that hospital ever since, except during a brief period immediately following his graduation.

He became assistant curator in the Pathological Museum in 1842, and lecturer on pathological anatomy. From 1852 to 1892 he was attending surgeon at the New York Hospital, and thereafter consulting surgeon. From 1860 he was a professor in the College of Physicians and Surgeons, up to 1871 being adjunct professor of the principles and practice of surgery; from 1871 to 1879 full professor, and from 1878 to 1888 professor of the principles of surgery.

His success as a practitioner began at an early period of his professional career. He was associated with Dr. Edward Delafield from 1849 to 1865, when Dr. Delafield retired. A partnership with Dr. Francis Delafield, son of his former partner, followed, and later Dr. Markoe's own sons became associated with him.

Before he became a professor at the College of Physicians and Surgeons, Dr. Markoe was for a time professor of anatomy at Castleton Medical College, in Vermont, and afterward professor of pathological anatomy in the University of the City of New York. At various periods he served as attending surgeon to the Nursery and Child's Hospital, the Mount Sinai, Bellevue, and Roosevelt Hospitals, and also as consulting surgeon at Mount Sinai, Woman's, Roosevelt, Orthopœdic, St. Mary's, Vassar, and the Nursery and Child's Hospitals, and to the Northern Dispensary. He was also a member of the staff of consulting physicians and surgeons of the New Dispensary.

Through the war he served as a surgeon in the Union Army, being at first stationed at Fortress Monroe and later at Fredericksburg. After the war he returned to his teaching, retaining from 1860 to 1870 the position of adjunct professor of surgery in the College of Physicians and Surgeons. For the next nine years he served as full professor, and during the rest of his active service he was professor of the principles of surgery at the College of Physicians and Surgeons. In these various capacities he became well known to very many New York physicians of the present day, and a considerable proportion of them had been at one time or another under his personal instruction. His genial personality was much appreciated by the students and his easy flow of language gave an interest to his lectures, which, taken with their practical bearing, always resulted in a lecture-room crowded with enthusiastic listeners. Dr. Markoe's telling descriptions of the processes of repair and his "healthy laudable pus" will always remain as pleasant pictures in the



THOMAS MASTERS MARKOE, M.D.

minds of his many students. Since his retirement in 1890, he has borne the title of emeritus professor of surgery at Columbia.

Dr. Markoe's published works have not been many, but they have been marked by high attributes. His work on Diseases of the Bone was an authority for many years.

Apart from his busy professional life much of his time was given to other interests. He became a trustee of the Astor Library in 1863, remaining as one of its directors until its absorption into the consolidated library plan. From 1891 to 1895 he was president of the Astor Library.

He was a member of the Academy of Medicine, County Medical Society, the Pathological Society, Medical and Surgical Society, Society for the Relief of Widows and Orphans of Medical Men, the Medical Journal Association, and of the Century, University, and Princeton Clubs; the American Museum of Natural History, and the Metropolitan Museum of Art.

Dr. Markoe married in 1850 Miss Charlotte Atwell How. They had five children. Two of the sons, Francis Hartman and James Wright, are physicians.

CORRESPONDENCE.

INSURANCE EXAMINERS' FEES.

To the Editor of the MEDICAL NEWS:

DEAR SIR: As far as I can judge the business manager of at least one of the most prominent life insurance companies of New York looks upon the medical department as little better than an unnecessary expense.

As local examiner I was advised that the fee for examination of risks up to $5,000 would be $3.00; it used to be $5.00. When I read the notice it recalled to my mind a factory where a cheap watchman was kept—the factory was burned down twice at night time. The insurance company that is parsimonious with its examiners should get bad risks in proportion to their parsimoniousness.

I accepted the appointment knowing all too well that the disunited medical men could not fight the Company and that if I did not take the appointment my neighbor would.

The next communication concerned the appointment of the local agent; if I suggested a good agent I was to receive a bonus of $10.00 for each $10,000 of insurance written. Now, this is surely asking me to act as agent and as examiner; if so much insurance is written then a commission is paid to me. I feel that this compromises my freedom as an examiner, to the possible detriment of the Company, but you say in a recent issue some companies are trying to insure everything that has one foot outside the grave.

Whilst attending strictly to my professional duties I unwittingly came within earshot of a meeting of the agents of this insurance company, in conference with officers from the head office. The agents were instructed to tell the doctors that the number of examiners was to be reduced, that the examinations were to be so much more numerous that the doctor would actually get more money under the $3.00 fee than under the $5.00. This is the new argument; we are to do our examinations by wholesale and therefore we must accept a smaller fee. Then the old argument was trotted out, that insurance fees were sure, no bad debts or, to put it plainly, the agents must blow the horn of their company to the tune that the company pays its lawful debts. This is a thing an honest man would not blow about very much. Further, in answer to questions, the head-office man instructed the agents that they must not pay the $2.00 out of their own pockets to the doctors as some had done; they must "support the head office" and the "head office would support them." Then, as a final *coup*, the instructor said in answer to a question that there might be special doctors whose influence must be considered and that in these cases arrangements might be made with the head office so that these especially influential doctors should receive fees at the old rates. Comments are unnecessary.

A. JACK.

July 23, 1901.

COLLECTIVE INVESTIGATION OF THE INFLUENCE OF THE SILVER-NITRATE INJECTIONS ON PHTHISIS.

To the Editor of the MEDICAL NEWS:

DEAR SIR: In 1892 the undersigned began a collective investigation of the action of cold in the treatment of acute pneumonia, and there is reason for believing that this procedure, which resulted in gathering four hundred cases of this disease thus treated with a death-rate of not quite five per cent., was an important factor in calling attention to the utility of that treatment and in introducing it to the profession of this country. That research was based on the conviction that no remedy can be called truly successful until it has passed the exacting crucible of clinical experience, and it is now proposed to apply the same ordeal to the silver-injection treatment of phthisis, which, in a large hospital, dispensary and private practice, reaching over a period of three years, and during which many thousand injections were administered, has given me greater satisfaction than any other method that I have ever employed. In keeping with the above expressed feeling a cordial invitation is herewith extended to those members of the profession who have the inclination and opportunity to investigate this method of treating phthisis and to whom a reprint on the subject, with full information and blanks to report cases, will be cheerfully sent on application.

THOMAS J. MAYS, M.D.

1829 Spruce Street, Philadelphia, Pa., August 15, 1901.

OUR LONDON LETTER.

(From Our Special Correspondent.)

LONDON, August 17, 1901.

THE "SILLY SEASON"—THE COMING REVOLUTION IN THE BRITISH MEDICAL ASSOCIATION—DISORDERLY SCENES AT CHELTENHAM—THE REFORM OF THE ARMY MEDICAL SERVICE.

WE HAVE now fairly entered on what journalists call the "silly season," when the gigantic gooseberry excites unholy jealousies in the agricultural mind and the great sea serpent disports himself in the newspapers. Parliament is on the eve of prorogation and physicians follow their patients out of town—to the seaside, to Switzerland and other Continental playgrounds, where they sit beside them at *table d'hôte*, realizing the millennial picture of the wolf lying down with the lamb. Hence the medical papers are duller even than usual—which is saying much. The only question that excites a languid interest in the few who concern themselves about medical politics is the projected reform of the British Medical Association. It is clear that, although the reformers carried all before them at Cheltenham, the scheme is looked upon with growing doubt and misgiving by many who cannot be regarded as obstinately conservative. They are coming to see that it is revolution rather than reform that is proposed, and that not merely the integrity, but the very existence of the Association will be imperiled if an imperfectly thought-out scheme is adopted. They declare that the matter was not properly discussed at Cheltenham, but rushed through by the simple process of muzzling the opposition. I was talking about the meeting a day or two ago to one of our foremost men, whose name is as well known on your side of the Atlantic as on this, and he gave me his impressions with a racy frankness which literary decency forbids me to reproduce. But the gist of his deliverance was that the reforming party were, with the exception of Mr. Horsley and one or two more, professionally as well as personally insignificant and that they only took to agitation because they had no practice to speak of. In fact they are, he said, the analogues of the unemployed *avocats* who have always been so dangerous a factor in French politics, and of the intellectual proletariate whose mischievous unrest in Germany was so much dreaded by Bismarck. Seeing no other chance of notoriety they bombard the editors of the medical journals with letters which when not silly are spiteful, and which if read by the outside public, must give it a very unfavorable opinion of the temper, logic, and even grammar of the medical profession. These effusions come from a small but noisy group whose obscure names have become a terror to quiet folk who seek for scientific edification in the medical journals. The amount of space occupied by the venomous vaporings, the droning and driveling, the braying and blustering of these fussy nobodies, goes far to justify the description of our two big weeklies as the "Great Unread." And it is the spirit of these men that is the active ingredient in the elixir of reform which is to be given to the British Medical Association to strengthen its Constitution! My friend added that of all the men of any importance whom he had met at Cheltenham, not one was in favor of the scheme which they thought, as he did, would probably ruin the Association. When I asked why, having the power to prevent its passing, he and his fellows did not take the trouble to vote, he merely shrugged his shoulders, and said, "How could any self-respecting person have anything to do with such a rabble?" There is the whole situation in a sentence. The great bulk of the members of the Association, including almost all the men whom it could least afford to lose, see clearly that it is threatened with wreck by being given over to the guidance of a few self-seekers and nonentities, but they will not lift a finger to save it!

What manner of men they are into whose hands the management of the British Medical Association is in imminent danger of falling was only too plainly shown at the annual dinner. This is generally a dreary but decorous festivity, but this year it was little better than an orgie. The conduct of many of those present was more like that of rowdy students than of professional men, and the interruptions were so loud and incessant that the speakers could not be heard. Fortunately the President is hard of hearing, and owing to this infirmity he was able to give the rein to his ultra-Ciceronian *copia fandi,* in blissful ignorance of the fact that no one was paying attention to his eloquent and loyal but immensely long orations. Professor George Dock of Michigan, who responded to the toast of "Our Guests," made caustic reference to the interruptions by telling a story of a speaker, who, in a like difficulty, said to one of the noisiest among the audience, "Do you believe in the efficacy of prayer?" To which the reply was, "Yes, I do." The next question was, "Do you believe in regeneration?" Whereto the answer was also in the affirmative. "Then," said the speaker, "the next time you pray, pray that you may be born again and stillborn!" The whole thing was a disgrace to the medical profession, and what made the scandal still greater was the fact that several Members of Parliament, and local magnates, clerical and lay, were present. What they thought of such an exhibition of disorderliness one hardly likes to conjecture.

The scheme of the Secretary of State for the reform of the Army Medical Service which a few weeks ago was submitted to a committee of experts is now ready. It will probably not be made public, however, for some time—possibly not till Parliament meets again in January. At any rate it cannot receive the Royal Sanction till Parliament has had an opportunity of discussing it, and there will be no opportunity till next session. I have heard on excellent authority that the new scheme is of a nature that will make it acceptable to the service and to the profession at large. The pay is to be on a scale that may fairly be called

liberal; the military titles which were wrung out of the War Office with such difficulty will be retained; opportunities will be given to officers of bringing their scientific knowledge up to date and increasing their practical skill; men of special talent will have better chances of doing good work than they get under their present *régime;* and the Director-General of the Service will have a seat on the Army Board when matters connected with the health of the troops are being considered. He will thus no longer be, as he is now, a mere departmental official, but the head of an autonomous branch of the army. His pay will be on a scale corresponding to his rank and official importance.

All this sounds very well, but we must not be too sanguine. The War Office has in past years shown a perfect mastery of the art of keeping the word of promise to the ear and breaking it to the heart. The success of the scheme will depend on the spirit in which it is carried out by the military authorities. But there is ground for hope that a better day is about to dawn for the medical service of the army in the mere fact that Mr. Brodrick, who has hitherto shown himself very decidedly unsympathetic towards the medical officers, seems, contrary to expectation, to have made a serious attempt to meet the demands of the profession. The hour has come and perhaps the man. They have not come too soon, for at the present moment there is not a single candidate for a commission in the Medical Service of the British Army, and I have reason to know that a large number of officers intend to retire as soon as they have served the twenty years needed to qualify for a pension.

TRANSACTIONS OF FOREIGN SOCIETIES.

French.

OPHTHALMIA NEONATORUM—ALOPECIA—ANEMIA IN PREGNANCY.

M. PINNARD, at the Académie de Médecine, July 16, 1901, read a paper in reply to a communication from the Minister of the Interior, which requested some action by the Academy as a body relative to adopting a code of instruction for midwives and nurses as to the prophylaxis and care of the various forms of ophthalmia and conjunctivitis to which the newly-born are subject. The paper closed with the following conclusions which were adopted: "For the decrease of the number of the blind the Academy of Medicine commends the following rules to the Government: First, let there be given at each house at the time of childbirth a circular, which shall give warning of the dangers and outcome and of the symptoms and causes of the ophthalmias to which the newly-born child is a victim. Second, measures must be taken to secure prompt announcement of all purulent ophthalmias without any exception whatever. Third, appointment at every public institution, whether purely a clinic or a maternity hospital, of an ophthalmologist, who shall care for those afflicted with the disease and instruct all undergraduate doctors, nurses and attendants in their treatment."

M. HALLOPEAU read a paper on the contagiousness of alopecia in behalf of M. DEZANTIÈRE in which the arguments against this theory were enumerated and then refuted by the well-known clinical features of this disease. There are many well-established small epidemics of alopecia in households, small villages, barracks, etc. Recently in Creusot there appeared a rather remarkable repetition of this feature in a school. Two children had gone to Paris and returned infected. After a time they passed the disease to many of the other scholars, then the teacher caught it and finally children in other schools. It is also easily demonstrable that the disease is parasitic in nature and progresses by auto-inoculation clinically. Although the parasitic character of this affection is admitted by the best authorities the infecting germ is not yet isolated. It is further established that it can not inoculate at a distance, but does so purely by personal contact. It is therefore unnecessary to exclude from schools, stores, etc., all those who have become afflicted, but it is desirable to have them wear some form of headdress which shall protect their associates from contact with them. A further change in their hygienic surroundings is hardly essential.

M. CHARRIN and M. GUILLEMONAT at the Académie des Sciences, July 8 and 15, 1901, read papers on the anemias of gestation, in which the following points were made: In general the blood changes due to pregnancy are too little studied and understood. In the first place, they made researches into the amount of iron. In pregnancy the iron salts of the spleen fall to 0.72 from a normal total of 0.96 and this results probably in favor of the child, because after birth it obtains comparatively little iron in the milk. The total iron salts in the maternal blood also undergoes much decrease; for example, in a normal woman, not pregnant, the total will be about 0.45, in the same woman with child it falls to about 0.38 to 0.34, in an anemic gravid woman the decreased total may range from 0.32 to 0.17. Further the alkalinity of the blood passes the normal of 1.20 to 2.00 by declining to 1.05 to 0.70 in the healthy and to 0.93 or even 0.53 in the anemic pregnant women or in those convalescent from phlegmatia. The mass of lime salts in commonly augmented. That of magnesia, on the contrary, becomes ordinarily much less. Coagulation in glass is as a rule a little more rapid than normally, the ratio being about 7 min. to 8 or 9 min. Urinary acidity rises from 1.20 or 1.45 to 1.57 or 1.95 and the total alkalinity of the saliva declines. In short, although the cellular elements show no important and constant changes the soluble parts of the blood indicate the common lien upon the system, and the waste of gestation. On the one hand, the loss in iron shows a certain degree of depreciation or disassimilation, and, on the other hand, it is found that after various changes there is during pregnancy a lessening of

the alterations in the blood which tend to the benefit of the child without much loss to the mother.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held May 16, 1901.

The President, Robert F. Weir, M.D., in the Chair.

The proceedings of the evening were opened by a memorial address on the late Dr. S. A. Purple, formerly President of the Academy of Medicine, delivered by Dr. Stephen Smith, his longtime friend and associate.

A Self-Made Man.—Dr. Purple, who afterward became one of the most prominent members of the New York Academy of Medicine, was born in 1822 of poor parents. He had to earn his own living besides helping pay off some debt contracted while the children of the family were growing up. At the age of twenty he entered Geneva Medical College and graduated after two years. For several years before his entrance into the medical school he had been reading medicine, keeping the book open in front of him while working at his trade. In order to pay the expenses of his medical education he worked on a farm for five months of each year and thus secured enough to support himself under the practice of the most rigid economy during the school term. He was graduated at the University of the City of New York and, by the advice of a clerical friend from his native town who had a charge in New York City, resolved to take up practice in the city.

Early Struggles.—When Dr. Purple started for New York to begin his practice he had only $25 in his pocket. In order to save expense he worked part of his way to the city on a canal boat, but even by so doing, when he reached town, he had only $17.50 as his capital. Of the struggle of his early years, he said very little. To friends he confessed that for the first three years he did not make his living expenses. He was able, however, in his fifth year to pay off most of the debts thus incurred. He became first an assistant editor of the *New York Journal of Medicine* and afterwards assumed editorial charge of the *Journal*. During his years of editorship, he contributed a number of articles himself and the high character of the contributions to the *Journal* show how wide was his acquaintance with medical men at the time, and how good his taste in selecting material.

Bibliophilic Work.—While in editorial charge of the *Journal* he became taken with the idea of making a collection of the serial medical literature of America. Incidentally he became interested in books on American history and his collection on this subject is extremely valuable and well known. He had a complete set of all the American medical periodicals that have ever been issued and made a present of them to the New York Academy of Medicine. This contribution laid the important foundation-stone of the present library of the Academy. His interest in the academy included every department of its work, however, and it is through his influence with Dr. Hosack that the Hosack contribution of $75,000 to the building fund of the Academy of Medicine was made. Dr. Hosack himself was deeply at enmity with a number of medical officials prominent in the Academy councils. When Dr. Purple first sugested the contribution Dr. Hosack would not listen to it. The unselfish spirit of the suggestion and Dr. Purple's friendliness for several years afterward won over Dr. Hosack to his purpose. After Dr Hosack's death, Mrs. Hosack offered to send her check for the amount, saying that it had been her husband's expressed wish that the sum should be given. While there was already a considerable sum in the building fund before the Hosack contribution, it was this magnificent donation that made the immediate erection of the Academy possible.

Portrait in Oils and Tablet.—A portrait of Dr. Purple, life size, in oil, was then unveiled. Dr. Smith presented it in the name of Dr. Purple's brother's family to the Academy as a souvenir of its dead President. The memorial tablet to Dr. Purple was erected at the entrance to the library. It contains the following inscription: "Samuel Smith Purple, M.D., Born June 24, 1822; Died September 29, 1900; Founder of the Library of the New York Academy of Medicine to Which He Gave Large and Valuable Contributions; A President of the Academy and an Earnest and Successful Worker in Its Interests; This Tablet Is Erected to Commemorate His Many Virtues and Rare Usefulness."

Sitophobia of Enteric Origin.—Dr. Max Einhorn read a paper on this subject. He said that while sitophobia of gastric origin is not uncommon, the fear of food because of intestinal distress after eating, though rare, is not infrequently seen. The word sitophobia has been taken already as the name of the condition in which patients refuse food when suffering from melancholia. This is really, however, not fear of food, but food refusal with suicidal purposes. It can be readily understood how sitophobia may endanger life when carried to excess.

Symptomatology.—A recent case in Dr. Einhorn's practice illustrates very well the symptomatology and general nosology of the disease. The patient suffered considerably from headache and obstinate constipation. He was a man of about forty years of age and the constipated habit had lasted for many years. When first seen about three years ago, cal-

cined magnesia was prescribed and large olive-oil injections advised. He became better under this treatment, but then neglected the diet regulations given him, failed to take the treatment regularly and became worse. He went to another physician, who advised large enemata of water. After a while these failed to help him and then he began to use various purgatives, his constipation constantly growing worse. It became so bad that he had a passage only every seven to ten days. This annoyed him very much and fearful lest the accumulation of material should do harm, he ate less and less. As a result extreme emaciation set in. He lost about forty-five pounds and when stripped every bone in his body could be counted. Sugar and albuminous materials especially seemed to cause him discomfort and serious inanition had resulted from the discontinuance of their use.

Special Therapeutics.—He was advised to use an injection of a pint of olive oil every day and sufficient calcined magnesia to secure a movement of the bowels. The amount of food that he should take was prescribed and his diet was gradually increased. Plain food was insisted on, but he was not allowed to refuse food because of his discomfort. Under this régime he increased nearly a pound a day for over a month and has now gained 32 pounds in all. His general condition is much improved, and his sitophobia has decreased with his increase in weight and the disappearance of his emaciation.
